A CLINICAL LECTURE ON PNEUMONIA.

Delivered to the Clinical Class in the Mercy Hospital of Chicago, May, 1882.

BY N. S. DAVIS, M.D., LL.D.,

PROFESSOR OF THE PRINCIPLES AND PRACTICE OF MEDICINE IN THE CHICAGO MEDICAL COLLEGE, AND SENIOR PHYSICIAN TO THE MERCY HOSPITAL.

(Reported for THE MEDICAL NEWS.)

GENTLEMEN: I intend to occupy your attention during the present clinic hour with the subject of pneumonia.

The patient before you is a laboring man, about thirty years of age, who has usually enjoyed good health. Nine days since he was much exposed to wet and cold, and was attacked with a well-marked chill, followed by pain in the left side of the chest, fever, and some cough. His symptoms continuing to increase, he was transferred to the hospital on the evening of the second day. At that time his temperature was 39.5° C. (103° F.); face flushed; skin dry; pulse 100 per minute, and moderately full; cough frequent, but not severe, and accompanied by a scanty expectoration of glairy mucus, slightly tinged with blood. There was slight dulness on percussion over the lower lateral and posterior part of the left side of the chest, and a distinct crepitant râle below the axilla of the same side. These physical signs, coupled with the general symptoms, indicated the existence of pneumonic inflammation occupying the lower and a portion of the middle sections of the left lung, just at the stage of progress when the primary engorgement of the capillary vessels had begun to cause active exudation of the corpuscles and plasma of the blood into the alveoli or air-cells and interstitial spaces of the lung structure. The following day the temperature increased to 40° C. (104° F.), and the pulse to 110 per minute. The face was more flushed; breathing shorter and somewhat stifled on account of a sharp or lancinating pain in the lower part of the left side, which had supervened during the latter part of the night. The expectoration was still scanty, but more stained with blood. The tongue was coated, bowels quiet, urine scanty and high colored, and the skin dry; percussion and auscultation showed an increase of dulness over the left side, from the line of the axilla to the diaphragm; slight crepitant râle along the upper part of the affected portion of the lung, with moderate mucous râles over all the lower part of the left side of the chest, and a slight pleuritic friction just above the attachment of the diaphragm. It was now evident that the pneumonic inflammation had fairly entered upon its second stage, or that of exudation and red hepatization, while a limited portion of the pleura had also become involved. Soon after his admission the evening previous, the house-physician had the left side of the chest covered with a linseed-meal poultice, and directed him a teaspoonful of the following mixture every four hours:

℞. Ammon. muri.	12.00 grammes,	.	ʒiij.
Ant. et pot. tart.	0.13 "	.	grs. ij.
Morph. sulph.	0.20 "	.	grs. iij.
Syrup. glycyrrhizæ,	130.00 c. c.,	.	ʒiv.—M.

At my visit the next day, finding the patient as just described, I advised a continuance of the emollient application over the chest, and of the formula just given; but directed to be given in addition a powder of sulphate of quinia 0.33 gramme (gr. v), and calomel 0.06 (gr. j), every four hours, making the powder and the cough mixture alternate two hours apart. The next day, which was the fourth after the initial chill, the temperature was only 39° C. (102.1° F.); the face less flushed; the skin moist; the expectoration more free and opaque, but still tinged with blood; the pulse more soft, but about the same frequency; little or no continuous pain in the chest, but still a sharp stitch in the lower part of the left side, on attempting to take a full breath or a free cough. Percussion showed no change in the degree or area of dulness, but auscultation detected neither fine crepitant râle nor friction, but a moderate mucous râle over the affected side.

I directed the same treatment to be continued, except the omission of the calomel from the powders, and the addition of a blister plaster, four by four inches, over the seat of sharp pain in the left side. The next, or fifth day of sickness, the records showed his temperature to have been 37.7° C. (100° F.) in the morning, and 38.5° C. (101.5° F.) in the afternoon; pulse 100 and soft; respirations 18 per minute; and chest free from pain, except on taking a very full inspiration; expectoration easy and quite free from blood; skin continued moist; urine more abundant; and one free evacuation of the bowels. Auscultation detected less mucous râles and a greater degree of expansion of the lung during inspiration, and yet there remained decided dulness on percussion over a limited portion of the lower and posterior part of the left side of the chest. The quinia powders were now reduced to 0.20 gramme (gr. iij) instead of 0.33 gramme (gr. v), and continued every six hours, with the cough mixture between, and milk and beef-tea more liberally for nourishment.

The patient continuing steadily to improve during the sixth and seventh days, the use of the anodyne expectorant was limited to one dose before breakfast and at bed-time, and the quinia to one powder after each meal-time. During the last two days, the eighth and ninth, he has been up each day; taken nourishment freely; had regular evacuations, but neither cough nor soreness in any part of his chest. In fact, he is so far advanced in his convalescence that he is now dressed ready to leave the hospital. I have called your attention to the details of this case, gentlemen, as a familiar example of one of the most important inflammatory affections you will meet in the ordinary field of general practice. Pneumonia, or inflammation of the parenchyma of the lung, is of frequent occurrence during the cold season of the year throughout the greater part of the temperate zone of the earth's surface. It usually prevails most during the latter part of winter and early part of spring. This is particularly true in those localities where periodical or malarious fevers prevail during the latter part of summer and autumn. It attacks persons at all periods of life, but is much more likely to prove fatal in early childhood and old age than in youth or early adult life. I have noticed that a very large proportion of the members of our own profession who die after fifty years of age do so from pneumonia.

The statistics presented by Dr. Samuel Forrey, in his valuable work on the climate of the United States, and its influence on the prevalence of diseases, appeared to show that pneumonia was most prevalent, and caused the highest ratio of mortality in what he called the middle climatic belt, which is that lying between the

thirty-fourth and thirty-ninth parallels of latitude. It is in that belt of country that we have long-continued and high summer heat, and though the winters are comparatively short, there are some days of intense cold, giving the thermometric combination of long and warm summers, short and cold winters, and wide range between the highest heat of summer and the coldest days of winter. Other circumstances being the same, it was where these characteristics were most marked that he found attacks of pneumonia and pleurisy to be numerically most frequent and most fatal. But in the northern belt, including all our country north of the thirty-ninth parallel, where the winters are more protracted, the summers shorter, with long and very changeable transition seasons, he found the highest ratio of prevalence of bronchitis, catarrhal affections, and rheumatism. The laws thus deduced by Dr. Forrey, chiefly from the statistics of the several military posts in the United States more than forty years since, have only been confirmed by the subsequent observations of others.

Etiology.—It is probable, however, that the general climatic features to which I have alluded, exert only a predisposing influence upon the whole population, while other causes acting more directly upon individuals are required to determine an attack. The most important of these direct exciting causes are doubtless exposures to cold and damp atmospheric changes, excessive physical exertion, intemperate habits, and lying on the damp ground, especially at night. A much larger number of cases occur in males than in females, and in those following out-door occupations than in those working in-doors.

Pathology.—Thus far, gentlemen, I have spoken of pneumonia as a simple local inflammation affecting the parenchyma of the lung; but there are many, at the present day, who claim that it is a general zymotic disease, and consequently to be classed with the idiopathic fevers. The principal reasons assigned for this view are that acute lobar pneumonia, pneumonitis, or croupous pneumonia, as it is variously designated by different writers, is accompanied by a fever which runs a definite course, is self-limited in duration, and does not always correspond in its severity with the extent or intensity of the inflammation in the lung. These reasons do not appear to me sufficient to sustain the conclusion drawn from them. It is true that pneumonia, like all other acute inflammations in vascular structures, runs a definite course, marked by a stage of intense engorgement or hyperæmia of the inflamed structure, a stage of exudation and more or less solidification, and a stage of resolution or suppuration; and the general fever rises with the first, reaches its acme in the early part of the second, and disappears with the beginning of resolution, or changes to a lower grade if suppuration supervenes instead of resolution. But the same is true concerning the fever that accompanies an acute pleurisy, or meningitis, or cerebritis, or hepatitis. Again, acute inflammation in any vascular structure is not a process that can remain stationary. Its first stage of vascular engorgement, if not speedily relieved, *must* be followed by exudation and more or less condensation, during which the greatest amount of heat will be evolved; and if the exudative material is not speedily removed by reabsorption, at the very beginning of which the fever heat would quickly disappear, it must degenerate into purulent, caseous, or fibrinous material, and either destroy life or undergo a slow process of repair. Consequently all acute inflammations in important organs are necessarily self-limited in their duration; and I have not been able to discover anything in the clinical history of pneumonia which, in this respect, differs from the history of other important local inflammations. On the other hand, it differs from the general or idiopathic fevers, in having no appreciable prodromic or forming stage prior to the appearance of the local phenomena; in being generally unilateral or attacking only one lung, or even a small part of one lung at a time, and in the fact that one attack does not in any *degree* lessen the liability to subsequent attacks.

It also prevails most at the same seasons of the year, and under the influence of the same exciting causes, as the inflammations of other parts of the respiratory apparatus, and not unfrequently in conjunction with them, as in pleuro-pneumonia, broncho-pneumonia, etc. I shall, therefore, continue to speak of the disease as one of the phlegmasiæ or important local inflammations. Clinical experience has shown that the inflammation commences in much the larger number of cases in the lower and middle lobes of one lung, and is often limited to these throughout its course. Sometimes it attacks corresponding lobes of both lungs at the same time, constituting double pneumonia, and cases are not wanting in which it commenced at the apex of one lung. If it supervenes as a complication with bronchitis, it is quite apt to develop in individual lobules of the lungs, constituting the variety called lobular pneumonia.

This occurs most frequently in young children. In whatever part of the lung structure the inflammation may commence, the essential pathological changes are the same as occur in all other acute inflammations. First, increased susceptibility or irritability of texture and intense engorgement of the blood in the vessels of the part. This constitutes the first stage, and usually lasts from one to two days, during which time many of the white corpuscles are attracted to the walls of the distended vessels, and the red adhere to each other in rows or chains, thereby adding to the obstruction of the circulation through the part. A continuance of this distention and obstruction of vessels and capillaries soon causes many of the corpuscles, with more or less of the plasma, to permeate the walls of the vessels into the interstitial spaces, the alveoli or air-cells, and bronchioles, thus excluding the air and rendering the whole structure more dense, constituting the condition called red hepatization, which is the second stage in the inflammatory process.

I shall not stop to discuss the question whether the process of exudation by which the inflamed structure becomes filled with the corpuscles and plasmic elements of the blood is one of cell proliferation, as claimed by Virchow and his followers, or one of exosmose aided by the affinity of the over-excited tissue for the blood elements, inasmuch as the practical results are the same; for neither the cell proliferation nor the exosmose would take place without the preceding irritability of tissue, and vascular fulness, and you may regard it as a rule, that in proportion to the intensity of the two last, will be the extent and persistence of the first. Thus far the pathological changes taking place in the inflamed lung are uniform in kind in all cases, differing only in the degree or amount of change. But the subsequent steps may lead to either of the following results, according to the coincidence of certain circumstances or variable elements that are liable to be present in each case: First, if the general properties of the tissues are natural, and the blood plastic and free from toxemic elements at the time of the attack, and the amount of exudation into the tissues is moderate, the diminished oxygenation and decarbonization of the blood will render it sufficiently sedative to check both the general fever and the local excitability, and the exudative material will undergo rapid disintegration and removal by absorption, constituting what is called resolution, and an early recovery. This is the result obtained in a large majority of the cases of ordinary uncomplicated pneumonia. Second, if the amount of exudative material filling the inflamed struc-

ture be so great as to over-distend the interstitial spaces and carry some of the corpuscular elements or leucocytes beyond contact with the living fibres, such elements will rapidly degenerate into pus corpuscles, and more or less suppuration instead of resolution will be the result, thereby protracting the patient's sickness, and often ending in a fatal degree of exhaustion. Third, if at the time of the attack, the patient has that deviation of the properties of his tissues and qualtity of his blood, from the normal standard which constitutes the scrofulous and tuberculous diathesis, then the exudative material that accumulates in the second stage will be very liable to undergo the caseous instead of direct purulent degeneration, causing the tissue to remain dense after the febrile stage has passed, and rendering the convalescence slow and incomplete.

In most of these cases, in a few weeks or months, the caseous material undergoes further degeneration into purulent matter, accompanied by all the phenomena of actively progressing pulmonary phthisis. Fourth, cases are met with, though rarely, in which the plasticity of the exudative material and the vital affinity of the tissue are such that more or less of the former becomes permanently organized and attached to the walls of the alveoli in the same manner as the plastic material thrown out upon the inflamed serous membranes, is organized into false membrane and made the bond of permanent adhesions. In these cases, the entire stages of the pneumonia pass rather slower than usual, and convalescence ensues. But on getting up, the patient is found to have undue shortness of breath and weariness on taking exercise, and a physical examination reveals diminished expansion of the affected side of the chest, diminished resonance on percussion, increased fremitus or vibration of voice, thus indicating density of the lung structure and diminished capacity "for air," without any other local or constitutional signs of phthisis. In this condition I have known a few patients remain for many years able to attend to a moderate amount of business with but little difficulty. And yet there is a tendency, in the greater number of such cases, to have further degenerative changes supervene sooner or later, in the primarily affected part of the lung, and causing them to be classed by some as chronic pneumonia and by others as fibroid phthisis. From this brief statement of the important pathological changes occurring in pneumonia, you will see that those of the first and second stages are the same in kind in all cases, varying only in degree; while those of the third stage vary much, both in the direction of the changes and in the results.

PURPURIC SMALL-POX:

A CASE, WITH AUTOPSY AND SEQUEL.

BY GEORGE H. ROHÉ, M.D.,

CLINICAL PROFESSOR OF DERMATOLOGY, COLLEGE OF PHYSICIANS AND SURGEONS, BALTIMORE.

ON the twelfth of March last, the steamship *Hermann*, with 727 emigrants on board, arrived at Baltimore, 18 days from Bremen. She had a clean bill of health to show; and though one death had occurred on the voyage, which raised a suspicion of small-pox, prompt prophylactic measures had been at once adopted, and no further indications of the disease had been observed. The quarantine physician carefully examined all the passengers, and those who showed no evidence of previous successful vaccination, were properly vaccinated. Most of the passengers were at once transported, *via* Baltimore and Ohio Railroad, to their destinations in the Western States,[1] while a comparatively small number remained in and about the city of Baltimore.

On March 15, H. Frederickson, a rather robust German, about forty years of age, who had been acting as a stoker on the *Hermann*, was admitted into the City Hospisal, suffering from what was recognized as a frank case of erysipelas. The erysipelatous inflammation was diffused over the head and greater portion of the upper extremities, having as starting-points three carbuncular swellings, situated on the upper lip, the right wrist, and left hand, respectively. These carbuncles, or boils, were opened, and discharged a considerable quantity of pus and necrosed connective tissue. He was immediately placed on the usual treatment for erysipelas —tincture of iron, in full doses—and the suppurating local lesions received proper attention. An improvement was rapidly manifest, and in the course of three days the erysipelas had nearly disappeared. On the following day, there was a renewed accession of the fever, with considerable headache, and some nausea and vomiting. The latter symptom was ascribed to the tincture of iron which the patient had been taking, and this was accordingly discontinued. During the afternoon of this day, a red rash—not elevated above the skin—appeared on the face, and by next morning had spread pretty well over the body. The eruption resembled scarlet fever, and was accompanied by some redness and swelling of the throat. During this day—the second of the eruption—small petechial spots were observed on various parts of the body, especially the abdomen and extensor surfaces of the arms. The headache and vomiting continued. No pain in the back was complained of.

On the third day, the petechial eruption became general, the spots in some places coalescing to form large, brown patches, not disappearing under pressure. Free perspiration had also been noticed. A small number of disseminated, small, conical papules were observed on the inner anterior aspect of the thighs, and believed to be lichen pilaris.

I saw him for the first time about one o'clock of this day, 21st, but had only a few minutes in which to make a very incomplete examination, being called away to assist in an operation, and promising to return and see him again in the evening. The history, as above detailed, I have obtained since that time. Within an hour after I saw him, he was taken with violent pain in the lumbar region, and died about 3 P. M. His mental faculties were unimpaired to the last.

The *autopsy* was made eight hours after death by Dr. Branham and myself, assisted by Drs. Van Note and Thomas, resident physicians at the hospital. The body was moderately well nourished. Rigor mortis was present in only a very slight degree.

[1] The *National Board of Health Bulletin* for April 8, contains a telegram from Dr. J. H. Rauch, Secretary of the State Board of Health of Illinois, conveying the information that a case of small-pox, by direct importation on the steamship *Hermann*, has developed at Ottawa, in that State.

The surface of the body was completely covered with petechial spots, which were aggregated in large numbers, especially on the chest, neck, the extensor surfaces of the arms and on the scrotum. In these localities they coalesced and formed large, brown patches, not disappearing under pressure. On the thighs were some papules of lichen pilaris.

The chest was opened in the usual manner. The subcutaneous connective tissue and fat were found infiltrated throughout with blood. The pleuræ and mediastinal tissue were also permeated in the same manner. All these tissues were softened and looked as if they had been soaked in bloody serum. At points, here and there, the color was darker, marking small hemorrhagic infarctions. About two ounces of bloody serum were found in the pericardium.

The pleuræ were soft, easily torn, and of a brownish color from the infiltrated blood. Pretty firm, recent pleuritic adhesions were found on the right side. The lungs were œdematous, and the right lung was adherent at the apex. The heart was empty, soft and flabby, and dark-red in color.

On opening the abdominal cavity, the omentum was found generally infiltrated with blood, giving it a rusty color. The liver of about the usual size, possibly a little enlarged, and somewhat softer than natural. The spleen was enlarged to about four times its normal size, very dark in color and very friable. The kidneys were enlarged to about twice the natural size, with ecchymotic spots in the tissue of the capsule and effusions of blood underneath the capsule. The surface of the right kidney presented disseminated ecchymotic spots similar to those on the surface of the body, and a large clot was found in the lower part of the capsule.

The mucous coat of the stomach was covered with disseminated ecchymoses. A large subserous clot of the duodenum extending about one and a half inches from the pyloric extremity of the stomach was also found.

The bladder contained a small quantity of bloody urine, but appeared otherwise healthy.

The right temporal muscle was permeated by blood, which also appeared in closely-disseminated spots throughout the other muscles of the scalp.

The dura mater was slightly thickened and the pia mater somewhat congested. The brain appeared normal, with the exception of some hypostatic congestion in the occipital region.

The spinal cord was not examined.

While making the autopsy, some points in the history of the case suggested to me Trousseau's description of one form of hemorrhagic small-pox, and led me to make a remark to that effect to Dr. Branham. But upon examining the arm and finding a good vaccination scar we dismissed the thought, and contented ourselves with simply noting the appearances found post mortem, believing that the purpuric condition could be accounted for by the blood-poisoning (erysipelas) through which the patient had just passed. A few days after the death of this patient, I learned for the first time that several cases of small-pox had been taken to the quarantine hospital from among the passengers on the same vessel in which Frederickson had arrived.[1]

On reviewing the clinical history and the post-mortem record, and comparing them with those characteristic of small-pox as given by good authorities, I could not at that time reconcile the discrepancies which seemed to me to negative that diagnosis.

Nothing further occurred to cause suspicion until April 2, when Dr. Van Note, who had been only occasionally present in the room when the autopsy was made, complained of indisposition, and in the course of the following day developed a pretty high fever with some mental disturbance. The notes of his case, for which I am indebted to Dr. J. W. Chambers, his medical attendant, are as follows:

April 2. 2.10 P. M.—Slight chill, followed by fever. At 9 P. M., temperature 104°, headache, and a diffuse redness over the entire body, less marked on the face than elsewhere. Ordered twenty grains of quinia every four hours.

3d. 10 A. M.—Temperature 104.5°, notwithstanding the heavy doses of quinia. Redness still marked, no headache, some pain in the back and knees. At 5 P. M., temperature 104.8°, pulse 120; slight mental disturbance when awaking from sleep. Continued quinia and ordered sponging every half hour. At 10 P. M., temperature 105.5°, pulse 130; delirious and very restless. Was wrapped in a wet sheet, and sprinkled with cold water every fifteen minutes for two hours. At the end of that time his temperature was 103.5°, and he expressed himself as being much more comfortable.

4th. 9.30 A. M.—Temperature 101.5°, pulse 100. The redness was less intense and a few papules were scattered here and there over the body. These symptoms seemed to justify the diagnosis of small-pox, and on the same day Dr. Van Note was removed to the quarantine hospital, his wife volunteering to accompany him as nurse. At this writing (April 20), he is entirely well and has returned to the city.

On April 3, a German sailor, who had for six weeks been an inmate of the City Hospital, undergoing treatment for a fractured thigh, and who occupied the bed next to Frederickson, was attacked with slight fever, headache, but no pain in the back, which latter symptom was present in but a slight degree on the next day, when I examined him carefully. He had no nausea or vomiting, and no free perspiration. On the third day (second of the fever), a bright-red rash appeared upon the face, extending to the neck and chest, but not invading the abdomen. The feet were also somewhat reddened, and by the following day an abundant crop of papules had appeared on the forehead, face, hands, and feet. The temperature had fallen to near the normal, but the pulse remained frequent and somewhat feeble in force. On April 5, this patient was also removed to the quarantine hospital.

On April 4 a third case developed, the symptoms being slight fever and vomiting, but no pain, either

[1] These cases were three in number. Two of them were of the petechial form and died soon after their admission into the hospital; but in these cases the characteristic pustular eruption of small-pox had appeared, rendering their diagnosis a matter of no difficulty.

in the back or head. By the following day a suspicious eruption had appeared, and he was also sent to the small-pox hospital at the quarantine station.

A boy, about twelve years of age, who had occupied a bed between the two foregoing cases, had slight fever and headache on the night of April 4, but appeared bright and well on the following morning, when he was discharged from the hospital and sent home. A day or two after, he was also sent to join the others at the quarantine station, having in the meantime developed an attack of varioloid, which proved, however, to be exceedingly mild.

The diagnosis of variola, either true or modified, was verified in all these cases by the subsequent history as recorded at the small-pox hospital.

Immediately upon the discovery of the nature of the disease from which Dr. Van Note suffered, all the patients in the City Hospital were vaccinated, the floors and woodwork thoroughly scrubbed, the walls whitewashed, the bedding changed and disinfected, and the beds and bedding occupied by the infected individuals destroyed. This was the end of what threatened to be the origin of a serious epidemic of the disease in a thickly populated and rather unsanitary part of the city. This gratifying result is doubtless due to the prompt vaccination and the thorough disinfection (cleaning) of the hospital as soon as the character of the disease was discovered.

In the text-books and treatises on the practice of medicine, this anomalous form of small-pox is so lightly passed over, that I have felt the importance of calling the attention of others to its occasional occurrence, in order that a more prompt diagnosis and the institution of efficient prophylactic measures may avert the consequences which resulted in the case here reported. Purpuric small-pox is comparatively a very rare form of the disease, though, like malignant scarlet fever and diphtheria, it occurs more frequently in some epidemics than in others. No one can question the very large experience of Trousseau, and yet it appears from his language that he rarely had opportunities for observing such cases. Kaposi,[1] who gives on the whole the best and fullest description of the disease I have met with, states that from 1866 to 1871, when small-pox might be said to be constantly epidemic in Vienna, he observed only one case of purpuric small-pox among 4,088 small-pox cases in hospital, and two cases in private practice. In 1874, however, he saw ten purpuric cases in 209 cases of small-pox.

Kaposi makes the remarkable statement that vaccination does not seem to be protective against this form of variola. In fact, purpuric small-pox occurs so often, proportionately, among vaccinated and revaccinated individuals, or such as have previously passed through an attack of small-pox, as to excite surprise. Again, it is not the old, decrepid, cachectic individuals of the lower classes, but more particularly well-nourished young persons, who live among the most favorable conditions, that seem to be especially liable to this violent form of the disease, which is almost without exception, fatal.

[1] Path. u. Therap. der Hautkrankheiten, Wien. 1879, pp. 235–239.

A form of small-pox in which hemorrhage takes place into the pustules, after the latter have become developed, is not so very infrequent. I recall a case that I saw in 1877, in this city, in which an attack of small-pox occurred for the third time—the last two attacks being in consecutive years—where the bullæ, of enormous size, were filled with blood. This attack proved fatal on about the fifth day of the eruption.

The scarlatiniform, or morbiliform, rash which generally precedes the outbreak of the petechiæ, is very deceptive, and may—and doubtless often does—lead to a diagnosis of scarlatina, rötheln, or measles. There is, at first, no means of differentiation, except possibly by the general symptoms, which are not reliable. One would not be led to suspect small-pox in a case like the one here reported unless in a time of general epidemic.

Curschmann[1] says of the petechial or purpuric variola: "Very soon (even in from eighteen to thirty-six hours) a diffuse, scarlatiniform—very rarely macular—redness invades the trunk and extremities, but leaving the face almost always exempt." There is in most cases great depression, nausea and vomiting, frequently bloody stools and urine, and stupor or marked mental derangement. The tongue is swollen and red, and the breath has a fetid odor.

In the case here reported, the redness first appeared on the face, and then spread to the trunk and extremities. Although nausea and vomiting were present, there were no bloody stools, the urine was not notably abnormal, there was no mental derangement, no glossitis, and no fetor oris. Even after death no fetid smell attached to the cadaver.

The post-mortem appearances in my case were also different from those given by the best authority as characterizing this variety of small-pox. According to Ponfick (as quoted by Curschmann[2]), the liver, kidneys, and spleen are not enlarged in subjects dead with purpuric variola. The spleen is said to be small, hard, dirty dark-red, sometimes with large white or yellowish follicles. Ponfick also states that the heart is contracted, firm, and brownish-red. The notes of the autopsy of my case show the liver to have been very slightly above the normal size, and not apparently much altered; the spleen was very large, dark-brown—almost black—and very friable; the kidneys were more than double the normal size, and with bloody infarctions in the substance of one of them. The heart was empty and uncontracted.

Hence it appears that, according to the clinical history and the post-mortem appearances in this case, the diagnosis of purpuric small-pox was by no means certain—in fact, hardly probable. And had it not been for the consequent cases, which could not be traced to any other source of infection, and the cases removed to the small-pox hospital, which had developed contemporaneously with the first case (Frederickson), it would have been impossible to definitely state the cause of death in this instance.

[1] Ziemssen, Cyclopædia, vol. ii., p. 354.
[2] Ibid, p. 387.

The discrepancies between the post-mortem appearances in this case, and those noted by such an accurate observer as Ponfick, are perhaps explained by the profound blood-change which the patient had undergone in the attack of erysipelas which preceded the variolous outbreak.

I would also call attention to the anomalous course followed by the other cases. The scarlatiniform rash, which was noted in most of the cases, seems to have been more frequently present than in previous epidemics here (that of 1872, for example). In Dr. Van Note's case this was so strongly marked as to lead to a primary diagnosis of scarlet fever. These cases show that the clinical history of small-pox is not in all cases so definite as to render the diagnosis easy. At the present day, when epidemics of small-pox are among the less frequent occurrences, and where they rarely reach any very wide-spread prevalence, it becomes especially important to pay close attention to such forms of the disease as are liable to be mistaken for other diseases, which are generally less serious in their consequences.

Another point of importance in connection with the case here reported, is the coexistence of two specific diseases in the same individual. Assuming the usual period of incubation of small-pox, the patient, Frederickson, must have been exposed to the infection about March 4. After that time he was attacked by erysipelas, and when the latter had disappeared, small-pox at once developed.

BALTIMORE, April 20, 1882.

IS TUBERCULOSIS A PARASITIC DISEASE?

BY GEORGE M. STERNBERG, M.D.,
SURGEON, U S.A.

IF the recently announced discovery by Koch of a bacillus of tuberculosis is fully confirmed by other competent observers, it will be admitted by all that we are indebted to the experimental method for a discovery of the highest importance to mankind, and that the labors of this ingenious and indefatigable country doctor have done more to establish medicine on a scientific foundation than have all the speculations of medical philosophers from the time of Hippocrates. The generalization, already made by many physicians in advance of satisfactory experimental evidence, that the infectious diseases are parasitic diseases due to the multiplication in the body of an infected individual—man or lower animal—of minute living organisms will no longer seem rash, even to the most conservative, if the truth of this discovery is confirmed.

The converse of this generalization, viz., that all parasitic diseases are infectious, is undoubtedly true, and if the time comes, as now seems probable, when we can say, with confidence, infectious diseases are parasitic, medicine will truly have established itself upon a scientific basis, and we may look for future triumphs in therapeutics corresponding with those already gained by preventive medicine, which is practically based upon a belief in the truth of this proposition.

That tuberculosis is an infectious disease is a truth that has been gradually dawning upon the medical mind, and which seems to be pretty well established independently of Koch's researches by the experiments of Villemin,[1] Tappeiner,[2] Cohnheim,[3] Toussaint,[4] and others, and by evidence of the kind which has been presented by Reich,[5] who traces tubercular meningitis in ten children, born of healthy parents during the years 1875 and 1876, to infection by a consumptive midwife, who was in the habit of kissing and fondling, to an unusual degree, the infants committed to her care.

No doubt numerous observers in various parts of the world are already engaged in a search for the bacillus of tuberculosis by the method which Koch has described, and we may look for very contradictory reports as to the results of such search. It must be remembered, however, that a negative result has but little value unless the method has been closely followed by one who has some experience in this line of investigation, and in the use of high powers. The fact that a discovery has been made—we shall assume that Koch's announcement is well founded until the contrary has been proved—by special methods of staining and cultivation in a field which so many others have explored in vain, shows how little importance can be attached to negative results as disproving the truth of the germ theory in any particular case, and how much depends upon experience and the perfection of methods in the prosecution of researches of this kind. Koch began this investigation as an *expert*, familiar from long practice with the technique of culture experiments and microscopical investigations with the highest powers. Probably no man living was better fitted by natural aptitude and past experience for carrying out an experimental research of this kind, and certainly very few would have been able to command as great confidence in the result announced in advance of confirmation by other observers. Still this confirmation is necessary in order to establish the discovery of Koch among the demonstrated truths of medical science. This is all the more essential, inasmuch as other observers, Klebs, Toussaint, have found in their experimental researches, organisms, *micrococci*, believed by them to be the agents of tuberculous infections, which differ morphologically from those—*bacilli*—described by Koch; and more especially because it has been demonstrated by repeated experiments that a disease closely resembling tuberculosis, if not identical with it, may be produced in animals by inoculation with a variety of organic products of non-tubercular origin, and even by the inhalation of inorganic particles. Thus, Brunet[6] inoculated seven rabbits with cancer, six with simple pus, and six with tuberculous matter. Of these, fourteen became

tuberculous, viz., six of those inoculated with cancer, three of those inoculated with pus, and five of those inoculated with tuberculous matter.

Shottelius[1] found that miliary nodules in the lungs resulted, in dogs, alike from the inhalation of the pulverized—spray—sputum of phthisis and of bronchitis.

Toussaint affirms that the tubercular deposits resulting from inoculation with non-tubercular material are not infectious, and that experimental pseudo-tuberculosis may be distinguished from tuberculosis proper by inoculation experiments, although the pathological anatomy of the two diseases is identical.

If we accept the view that the tubercular nodules are of inflammatory origin, we can readily understand how both living and non-living particles may give rise to local inflammatory processes, resulting in similar pathological products, and the infectious or non-infectious character of these products would then be explained by the presence or absence of living organisms, in accordance with the views of Burden-Sanderson,[2] who says, "*Whenever an inflammation becomes infectious, it owes that property to chemical change in the exudative liquid, of which the presence of microzymes is a necessary condition.*"

The weight of experimental evidence seems to the writer to favor the view that the specific properties of Koch's bacillus depend upon its ability to locate itself in certain situations, rather than in any power to produce a special kind of inflammation, giving rise to products having specific characters. If this is the case, we should expect that other organisms capable of locating themselves in the same situations would likewise give rise to tubercular neoplasms. In a recent communication to the French Academy of Sciences, we have evidence presented that such is the case.

M. Laulainé,[3] in a note presented by M. Bouley, on the 2d of January of the present year, makes the following statements:

The author had recently observed in the lungs of a dog the alterations produced by the eggs of a nematoid worm, the *strongylus vasorum* (Baillet), which possess great interest, because of their apparent identity with those of tuberculosis. These *strongyles* in the adult state live in the right ventricle and in the larger divisions of the pulmonary artery. Here they are massed together in balls of greater or less magnitude, which consist of individuals of both sexes. These masses are restrained from being washed away by the blood-current by anastomosing fibrous bands, which are developed as the result of an endarteritis, which is infallibly produced by the presence of the parasites. The fertilized eggs emitted by the females in these tangled masses in the central part of the circulation, are carried along by the current to the smallest arteries and capillaries, where they are arrested and where the embryos are born. These emigrate immediately to the smaller bronchial tubes. The lungs of dogs infested with this parasite are filled with fine gray granulations, the histological characters of which are described by the author as follows:

"The eggs and the embryos arrested in the smallest *arterioles* become the point of departure of a nodular arteritis, presenting in its structure all the characters assigned, since Köster, to the elementary follicles of tuberculosis. At the centre of each nodule is found an egg or an embryo enclosed in a giant cell, this is surrounded by a more or less abundant collection of *epithelioid* cells or by an exterior embryonic zone which tends frequently to become fibrous."

The author points out that this pseudo-tuberculosis affects especially the base of the pulmonary lobes, differing in this respect from true tuberculosis which is located by preference at the summit.

The present writer intends to repeat the experiments of Koch, if circumstances and the limited facilities now at his command enable him to do so, and if any results are attained worthy of record, proposes to communicate them in a second paper to which this will serve as an introduction.

MEDICAL PROGRESS.

Ovariotomy in Berlin.—In a recent number of the *Berliner klin. Wochenschrift* Prof. Schroeder gives a brief summary of 300 cases of ovariotomy performed by him. His result as to mortality is this—seventeen deaths in the first hundred cases, eighteen in the second, and only seven in the third. This mortality of 7 per cent. in the last hundred, Prof. Schroeder proceeds to minimize further, by saying of three of the fatal cases that death was not due to ovariotomy *per se*. In one of these there were several uterine myomata, and he attributes the peritonitis which in this case carried off the patient, to the diminution in the blood-supply of these tumors caused by the ligatures. Two others died suddenly from heart-disease, on the eighth and fourteenth day respectively after the operation. One in the second hundred died on the eighth day from the same cause. Another case, in which a portion of the cyst had to be left behind, died in the sixth week. The three others died from septic peritonitis. No case in which the operation was simple ended fatally. With regard to this method of viewing the cases, although we admit that Prof. Schroeder is quite justified in taking the attitude he does, yet it is not the one best calculated to help forward science. An operator, in judging his own results, ought to accept no excuses. He should regard every death as due to his own fault—either directly, from some error in the operation or the after-treatment; or indirectly, from his not having foreseen the state of things which led to a fatal termination. He should, without mercy to his reputation, include all incomplete operations, or cases in which erroneous diagnosis led to failure. It is only thus that he will make his mistakes into warning lights, marking out the path of safety more precisely than before. These remarks, however, apply little to Prof. Schroeder himself; we make them for the sake of those who, we fear, may be tempted by his example to try and explain away their death-rates. As our readers will expect from his good results, Prof. Schroeder operates with all antiseptic precautions, including the spray. He thinks it would be to the advantage of patients if all these

operations were left in the hands of specialists, for it is only experience that can give fertility in resource when difficulties have to be overcome. He now thinks it possible to remove *any* ovarian tumor; and he mentions two cases in which at an early period in his career he opened the abdomen, but gave up the attempt to remove the tumor, and subsequently, when his experience was larger, again opened the abdomen and successfully extirpated the disease. Age he regards as no contra-indication; he has removed one tumor from a child of thirteen, and another patient left the hospital convalescent on the day before her eightieth birthday.—*Med. Times and Gaz.*, May 6, 1882.

PHYSIOLOGICAL ACTION OF BOLDO.—M. VERNE made a series of experiments on himself with boldo (the leaves of the *boldea fragrans*, or *peumus boldus*), and came to the following conclusions regarding its action (*Bull. Gén. de Thérap.*). The essential constituents of boldo, including boldine and some aromatic principles, are eliminated by the urine. Boldo does not influence the circulation, the temperature, or the quantity of urine secreted. It augments to a sensible degree the elimination of urea. The author thus places it alongside coca, the action of which on nutrition is similar. He notes also that he has frequently observed, both in himself and others, slight excitement during the first day that the medicine was taken; but this soon disappeared, and not uncommonly patients recovered sleep which they had previously lost through anæmia or some other cause which destroyed the equilibrium of the nervous system.—*Glasgow Med. Journ.*, May, 1882.

LUPUS ERYTHEMATOSUS.—DR. TH. VEIEL draws the following conclusions from his study of this subject:

1. Lupus erythematosus is an independent disease, and not a form of lupus vulgaris.

2. A connection between lupus erythematosus and scrofulosis, tuberculosis, and syphilis cannot be established.

3. The affection of the sebaceous or sweat-glands is an accidental accessory phenomenon. The essential nature of lupus erythematosus consists in the pathological alterations which are found along the course of the bloodvessels.

4. No remedy has as yet been discovered, the internal use of which produces a cure of lupus erythematosus.

5. The most efficient local remedy for lupus erythematosus is multiple scarification, in connection with subsequent cauterization with chloride of zinc.—*Arch. of Dermatology*, April, 1882.

THE INFLUENCE OF THE PNEUMOGASTRIC NERVE ON RESPIRATION.—ROSENTHAL has been devoting a great deal of attention to the innervation of the respiratory movements, and from some recent experiments (*Arch. f. Anat. u. Phys.*, 1882) concludes that:

1. Fibres are to be found in the vagus, probably arising in the lungs, whose irritation produces weaker and faster respiratory movements by acting on the respiratory centre; strong irritation of these fibres arrests respiration in inspiration. He calls these the "regulating fibres."

2. Fibres were also found in the superior laryngeal nerve, whose irritation slowed the respiratory movements and made them deeper, or by strong irritation entirely arrested them. He calls these the "respiratory inhibitory fibres."

3. Irritation of the inferior laryngeal nerves causes arrest of breathing in expiration. Since this effect can only be produced by strong irritation, and not in narcotized animals, or in those in whom the cerebrum has been removed, they cannot act in the same manner as the above-described inhibitory nerves, and are probably merely sensory fibres with only an indirect influence on the respiratory movements.

4. Large doses of chloral (0.3 gramme injected into a vein) prevents the action of the regulating fibres, but does not interfere with that of the inhibitory fibres.—*Centralb. f. d. Med Wissen.*, June 3, 1882.

CRICO-THYROID LARYNGOTOMY.—M. RICHELOT reports a case of laryngotomy performed by opening the crico-thyroid membrane as a preliminary to excision of the tongue and part of the lower jaw for extensive epithelioma, and believes that this method of opening the air passages is in adults less dangerous than tracheotomy, and has many advantages.—*L'Union Méd.*, June 1, 1882.

ATROPIA IN THE TREATMENT OF CORYZA.—DR. GENTILHOMME has used atropia, in doses of one-half a milligramme in pill form, in a number of cases of coryza, and think that it is extremely efficacious in both acute and chronic coryza, particularly at the close of an acute attack when associated with bronchitis.—*Union Méd. et Sci. du Nord Est*, May, 1882.

TREATMENT OF CHANCRE BY GLYCERINUM BORACIS.—DR. GEORGE THIN recommends the constant touching of chancres with glycerinum boracis, and reports three cases in which it appears to have produced good results.—*Lancet*, May 27, 1882.

EMBOLISM OF THE CORONARY ARTERIES.—DR. POPOFF (*Vratch*, 1882, No. 2) describes the following case of this rare affection. The patient, a sailor, aged 53½, had had an apoplectic attack about one and a half years previously, at which time aortic insufficiency had been recognized. One morning there suddenly appeared sickness and vomiting. When immediately seen by the author, the patient bore an appearance of extreme horror, and was sitting, being unable to lie down. His extremities were cold and covered with clammy perspiration; his lips were livid. Examination showed complete absence of the pulse in all accessible arteries, and neither apex-beat nor heart-sounds could be detected. The ear, applied to the cardiac region, could hear only a kind of cardiac tremor, which was very like the sound of a vibrating steel-plate. There was no loss of consciousness. Respiration was regular and rhythmical, not exceeding eighteen to twenty. Twenty hours after the first symptoms, the patient was dead. This affection was diagnosed during life, though the author had never before met any similar case in his practice. The alternative in diagnosis lay between embolism of a branch of a basilar artery, and embolism of the coronary arteries of the heart. Dr. Popoff accepted the latter alternative, on the ground (1) of the regularity and rhythmic character of the respiration; and (2) of the enfeeblement of the heart's action, which was transformed into simple oscillatory movements. Necropsy confirmed the diagnosis. There were found sclerosis of all the bloodvessels at the base of the brain; anæmia of the brain; venous congestion of the cranial bones and meninges; old apoplectic foci, in the stage of softening, in the right corpus striatum, and the posterior horn of the right lateral ventricle; pericarditis, endocarditis, and myocarditis; ossification of both coronary arteries of the heart, with complete thrombosis of their longitudinal branches; œdema of the lungs, and venous hyperæmia of the spleen, the liver, and the kidneys. The cardiac symptoms observed in the case are in strict harmony with the results of Samuelson's experiments on ligature of the coronary arteries in rabbits.—*London Med. Rec.*, May 15, 1882.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE, ... $5.00.
SINGLE COPIES, ... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made at the risk of the publishers, by forwarding in REGISTERED letters.

Address, HENRY C. LEA'S SON & CO.,
Nos. 706 & 708 SANSOM STREET,
PHILADELPHIA, PA.

SATURDAY, JULY 1, 1882.

HEAT-EXHAUSTION AND HEAT-STROKE.

AT the approach of Milton's "solstitial summer's heat," it behooves us to be prepared for the consequences of prolonged high temperature. By those who preserve tranquillity of mind and a healthy state of the bodily functions, summer's heat and winter's cold are alike faced with impunity. The regulating mechanism by which the temperature of the body is maintained at a uniform level, what changes soever may occur without, does not fail in the performance of its beneficent task. When, however, disturbing influences are introduced into the daily life, or the mechanism of heat production and heat elimination is disordered by disease, serious consequences ensue, and he can the better encounter them who has formulated in his mind well-defined principles of action.

A distinction of immense practical importance exists between *heat-exhaustion* and heat-stroke, or *coup de soleil.* It is much to be feared that this difference too often passes unregarded, to the serious detriment of the patient. Heat-exhaustion, as the term implies, means a sudden cerebral anæmia produced by work or muscular exercise in a high temperature. Heat-stroke, or sun-stroke, signifies the sudden access of unconsciousness with high febrile heat. In the former the body is cool, the skin moist, or wet with perspiration, the pulse small, feeble, and low in tension, the muscular system relaxed, the pupil dilated, and the mind feeble, but consciousness is not lost, or is restored after a syncopal state of brief duration. In the latter there is profound unconsciousness, contracted pupil, injected conjunctivæ, the skin is hot and usually dry, the temperature high or hyperpyrexial, the pulse rapid and its tension high, and the muscular system is often convulsed and tends rather to rigidity than relaxation.

Upon a due recognition of these antipodal states depends the success of the treatment instituted. If heat-exhaustion be treated by the measures proper in thermic fever, or *vice versa*, the result will be disastrous. It follows that a careful study of the conditions present, should precede any therapeutical measures. If the case be one of heat exhaustion, the patient will probably be able to swallow. Repose in the shade in the recumbent posture, and a few drops of laudanum in a tablespoonful of whiskey or brandy, will quickly bring about restoration.

The conditions are greatly more complicated when we have to deal with the unconsciousness of true sunstroke. Our readers need hardly be told that there are several varieties and grades of heat-fever. That there is a fulminant form in which paralysis of the heart ensues so suddenly that no therapeutical measures can be instituted, is a fact which invests the prodromes when they do occur with peculiar interest and importance. Usually, however, when the physician is summoned the character of the case is decided; the patient then lies unconscious and cyanosed, the breathing is shallow or stertorous, the muscular system is in a state of resolution and all the reflexes are abolished, and the temperature is above the danger line, somewhere from 105° to 110° Fahr. In a few cases, in addition to these symptoms, clonic convulsions, or epileptiform attacks, or tetanic rigidity of the muscular system occur.

As the mortality of heat-fever is great, its course rapid, and the measures of relief of uncertain value, prophylaxis assumes a high degree of importance. As those who have exhausted the nervous system by various excesses are the chief victims, obviously the great measure of prevention is sobriety. It is not alone alcoholic excess that predisposes to attacks. Venery, late hours, bad air, excessive tobacco-smoking, are amongst the depressing causes to which attacks of heat-fever have been attributed. Exposure to the direct rays of the sun is not alone necessary; to the existence of a high temperature of the atmosphere in general, and a disturbed state of the relations between heat production and heat elimination effected by the causes above mentioned, must the attacks be attributed, and hence the measures of prophylaxis must include the means of avoiding both sources of danger. Another pathogenetic factor, about which, however, differences of opinion may well exist, is the sudden ingestion of a large quantity of ice water. The extreme cold acting on the terminal filaments (end organs) of the pneumogastric nerve, may excite a sudden "restraint" and paralysis of the heart. There is, however, another

explanation of the sudden death which sometimes ensues after swallowing an enormous volume of water. The free perspiration has so diminished the quantity of water in the blood, that absorption becomes excessively rapid, and the red blood-globules are damaged and suddenly cease to functionate. If these factors exert an influence, as seems probable, it is, obviously, the part of wisdom for those working in a high temperature to drink water slowly and moderately.

In the case of true heat-stroke the victim should be at once removed to the shade, to as cool a spot as practicable, and should have cold water thrown on him, be rubbed with pieces of ice, and have ice applied to the head and spine. In the convulsive form of attack, the hypodermatic injection of morphia is indicated; indeed, no measure appears to have relieved a larger proportion of cases of all kinds. The administration of quinia by the subcutaneous method is, also, a remedy of great value for the reduction of the abnormal heat. It is probable that the subcutaneous injection of pilocarpine will prove very useful in cases with a dry skin and suspended action of the kidneys. The inhalation of chloroform has succeeded in the cases characterized by great restlessness, and by convulsions. The hypodermatic injection of chloral (ten grains to twenty grains), repeated as necessary, will also be found to lower the temperature and allay excitement, and, it may be, restore consciousness. We especially commend to our readers these new expedients, which promise so much utility in the treatment of a condition hitherto but little amenable to any therapeutical measures.

DROWNED OR POISONED?

EXPERTS are still puzzling Court and jury with the question of Jennie Cramer's mode of dying. In a recent issue we reviewed the subject of arsenical poisoning. As the signs and symptoms of drowning have been newly taken up by some experts for the defence and in rebuttal, it may be useful to call attention to the principal points connected with that topic.

Was Jennie Cramer dead when her body was deposited in the water? was she stunned by the shock of the fall in the sand? or did she die by drowning? Sufficient arsenic to kill was found in the body, and in such a state of diffusion as to warrant the inference that this poison had been taken in solution, and for a short time previous to death. The absence of inflammation of the stomach was held to be one of those exceptional cases, but not uncommon, in which the force of the poison was expended on the nervous system.

Some sand was found in the gullet, but none in the stomach, and no sea-water in the stomach or lungs. This negative fact was held by the prosecution to destroy the theory of death by drowning. The presence of sand in the fauces was explained by the fall of the body in shallow water, the face being projected in the ground. Prof. Harris, of Harvard College, summoned for the defence, maintained that the presence of water in the lungs and stomach was not necessary, but that the half pint of reddish fluid found in the pleural cavities, and the dusky hue of the countenance, were conclusive of death by drowning. The reddish fluid, he maintained, was water which had percolated through the lungs, and that no water was found in the stomach was due to the fact that Jennie Cramer, in precipitating herself into the shallow water at Savin Rock, was stunned. Against Prof. Harris, of Harvard, was summoned Dr. Wooster Beach, Deputy Coroner of New York. Whilst Dr. Harris had inquired into 140 cases of drowning, and had made autopsies in 40 of them, Dr. Beach had examined 850 cases of drowning, and had made autopsies of 50 to 75. Justified by so large an experience, Dr. Beach was disposed to speak by authority. He finds the presence of water in the lungs and stomach necessary in cases of drowning, and has but little confidence in the value of a reddish fluid in the pleural cavity as a sign, since this is so often present in death from any cause, if decomposition has begun.

The Boston and New York experts were thus placed in direct antagonism. To those unacquainted with the nature of such observations, an opposition of opinions is an indication of the insincerity of expert testimony, and of the uncertainties of medical science, whereas the fact is, that both experts were correct in their expressions of opinion. The opposition is apparent, and due to the mode in which such testimony is brought out by the prosecution and by the defence. No case could better exhibit the mechanism by which experts are made to differ. Both sets of facts may be true of cases of drowning, and hence in any special instance the associated circumstances possess a high degree of value. The attorneys for the prosecution on the one hand, and for the defence on the other, use experts to develop the facts necessary to their own side. Hence in this case, whilst the prosecution wished to show that Jennie Cramer was poisoned by arsenic, and her body afterwards thrown into the water, the defence were equally interested to prove death by drowning. The appearances were not characteristic, and hence the opportunity afforded counsel to develop contradictions which are merely apparent, and which are readily reconciled. If the object of the investigation were to ascertain the truth, an expert selected by the Court could state the positive and negative facts bearing on the theory of drowning.

It is fortunate that the medical profession has been well represented. The gentlemen appearing on both sides have exhibited an intimate acquaintance with the subjects on which they testified. That they appear in an aspect of antagonism is not a reflection on them, or on medical science, but is due simply to the fact that the case presents many points of obscurity, and is in no respect typical, whence it follows that negative evidence approaches the positive in value.

THE CHLOROFORM DISCUSSION IN THE PARIS ACADEMY OF MEDICINE.

For some weeks past the Académie de Médecine of Paris has been discussing the dangers of chloroform and the mode of avoiding them. As a ghastly commentary on the debate, during its very continuance, and in France alone, three cases of death from chloroform were published, the relation of one of which appropriately closed the discussion: A man aged thirty-one, in perfect bodily health, but who suffered from an intractable sciatica. Dujardin Beaumetz stretched the nerve by forced extension of the leg. The chloroform was pure, was given on a simple compress, and intermittently, and yet before 3ijss had been inhaled he suddenly died, and neither the reversed vertical position, artificial respiration, electricity, nor tracheotomy, was of the slightest avail.

The reply of Gosselin, that the more such accidents multiply the more necessary it is to establish precise rules for the administration of the anæsthetic, is surely not enough. The more such accidents multiply the more diligently should the search for a *safer anæsthetic* be the object before us. As M. Rochart well said, the only question during the discussion had been that of death—death by asphyxia, death by syncope, death by intoxication, death in the first period, death in the second, "partout et toujours la mort;" and Le Fort reported that he had himself statistics of two hundred and fifty deaths from its use.

Ether seems scarcely to have had a champion. True, Vulpian said it was used in the laboratory and on animals because of its greater safety, and Panas recommended its use in the profoundly anæmic. But no one seems seriously or vigorously to have asserted its claims as the safest and, therefore, the best anæsthetic. Clearly Japan is not the only country that needs a medical missionary.

THE PENNSYLVANIA COMMISSION TO INQUIRE INTO THE LUNACY LAWS.

We are very glad to see that Governor Hoyt has appointed Dr. Jos. A. Reed, of Pittsburg, Gen. Hartranft, Messrs. Richard C. McMurtrie, George L. Harrison, and L. Clarke Davis, and Drs. S. Weir Mitchell and J. T. Rothrock, a Commission to inquire into the lunacy laws of this State, and to report in time for their recommendations to be embodied in his message to the Legislature at their session during the coming winter.

The *personnel* of the Commission could not be better. Of the medical men we need not say a word; their names are a sufficient guarantee that good judgment, independence, and experience will mark all their recommendations. Law finds one of its foremost representatives in Mr. McMurtrie; Mr. Harrison, so long connected with the Board of Public Charities, will bring a large experience to the work; Gen. Hartranft will represent the political side of the question, if such there be; and Mr. Davis well represents the press.

We trust that the Commission will make some of the radical changes already alluded to in the columns of The News. Especially as to the commitment of the insane, whether in public or private asylums, the blanks should be far more specific, and the qualifications of the certifying physicians should be clearly defined. We trust also that they will provide for frequent and thorough inspection, especially of private hospitals, by regularly appointed and well qualified Commissioners in Lunacy, after the English model.

MEMORIAL CHAIRS IN OUR MEDICAL COLLEGES.

We are very glad to see movements in both the University of Pennsylvania and the Jefferson Medical College to endow memorial chairs, as is so commonly done in the literary and theological departments of our colleges. In the former, as was seen by the circular we published last week, it is proposed to raise $100,000, the income of which shall be paid to Prof. Joseph Leidy during his life-time, and at his death it shall be devoted to the maintenance of the Joseph Leidy Professorship of Anatomy. In the latter it is proposed to raise $50,000 to endow the S. D. Gross Professorship of Pathological Anatomy. It is eminently fitting that two of our most distinguished medical men should be so honored. Modesty and merit both claim such recognition for them. It is an example to be followed in many other cases. John Rhea Barton is the only medical name at present so commemorated in this city. Why should not the memory of such an eminent surgeon as the late James R. Wood be so perpetuated; or, in time to come, the representative of Boston surgery, who, to the regret of the whole profession, has lately resigned his chair, and many others, in various medical centres, whose names are indissolubly connected with their chosen chairs of teaching?

Might not some of our rich men—yet so modest that they would not even wish their own names to

be attached to a chair—find in this proposal a mode of solving the difficulty, and at the same time of honoring men dear to science; rich in ideas, rather than in shekels.

GUITEAU—FINIS.

PUBLIC and professional interest is attracted anew to the subject of Guiteau's mental condition by the final appeal to the President which has just been made in his behalf. The late efforts of some eminent New York psychiatrists and neurologists have been not without effect. Any change of opinion wrought by them is, however, limited to the small number of specialists, medico-legal experts, and humanitarians, who subscribe to the doctrine of moral insanity, and who are, therefore, brought to recognize the existence of that form of mental disorder of which Guiteau furnishes an excellent example. Without questioning the justice or the propriety of the position, we may, at least, appeal from the conclusion to which a too partial adherence to their views conducts them.

We believe that a true conception of right and wrong, and a just appreciation of the consequences which must follow from pursuing the wrong, should be the test of legal responsibility. Such is the view of the legal profession. The class of alienists above referred to have, however, followed their opinions to their logical conclusions, and have held, and do now hold, the irresponsibility of the subjects affected by the so-called moral insanity.

Although abstractly regarded, their position is correct, there are so many practical obstacles to the application of this view that the safety of society, we are firmly convinced, requires us to adopt the legal view of criminal responsibility. The loose way in which the criminal insane are held in confinement, the liberty accorded to so many dangerous lunatics, and the ease with which a man with means may free himself from asylum restraint, render the application of the doctrine of moral insanity, as held by some alienists, in a high degree injurious to the public. The safety and happiness of the people are far more important than the mere restraint for life, or than the death of an occasional lunatic who is conscious of the nature of his crimes, although influenced to their perpetration by some form of delusion. Humanitarian considerations and an obstinate adherence to views which seem to be a logical outcome of theoretical opinions, ought to yield to the far higher claims of society for protection against an enemy whose existence operates as a constant menace to the happiness and well-being of any one who may happen to cross his path. Guiteau suffers the penalty for a crime of whose nature and consequences he was fully aware.

IS IT TRUE?

IN an advertising announcement of a book on opium-smoking in America and China (mark the association), we find the following startling statement:—

"It is estimated that there are at least six thousand men and women who are slaves to this vice. It is daily spreading with frightful rapidity, and bids fair to outrival every other form of the opium habit."

To give emphasis to this alarming declaration, the publishers' advertisement is embellished with a sensational cut entitled a "Group of American Opium Smokers." They are represented in impossible attitudes—a woman in the act of taking a pipe from a man engaged in lighting the already filled bowl, reversing the garden of Eden scene, in which the woman tempts the man. Barring the unseemly character of the advertisement, we may, at least, be permitted to ask the question, is this true? Is it true that so many Americans—we do not mean Chinese in America—are now addicted to this vice? Is it true that this opium-smoking is "spreading with frightful rapidity?" The Messrs. Putnam declare it formally, and over their own signature. Without presuming to question their truthfulness, we may at least inquire, where is the evidence? Who has collected the statistics?

THE reporters, eager to impart an interest to their communications, do not spare the experts who are so unfortunate as to testify on the Malley trial. In the report for June 22d, we find that Dr. Pliny A. Jewett is entitled "the Jumbo of New Haven therapeutics."

It is also stated that Dr. Jewett, and Dr. Beach, of New York, "listened to the Harvard Professor with corrosive interest," and that the "Yale Professors were out in force, awaiting an opportunity to trip the gentleman from Harvard."

In this, and many other ways, medical experts are belittled, and their science made to appear false or unsettled.

PROF. HARRIS, of Harvard College, has, it appears, written several plays, which have been successful. The District Attorney used this fact to disparage his professional acquirements.

Mr. Doolittle (insultingly).—"You have written plays which were produced on the stage?"

Dr. Harris.—"I have."

Mr. Doolittle.—"That's all."

Nothing more was necessary to give the jury an unfavorable impression of Dr. Harris. Experts should govern themselves accordingly.

SOCIETY PROCEEDINGS.

AMERICAN NEUROLOGICAL ASSOCIATION.

Eighth Annual Meeting, held at New York, June 21, 22, and 23, 1882.

(Specially reported for THE MEDICAL NEWS.)

JUNE 21ST. AFTERNOON SESSION.—The American Neurological Association convened in the Hall of the New York Academy of Medicine, June 21, 1882. In the absence of the retiring President, Dr. Roberts Bartholow, the Secretary, Dr. Seguin, called the Association to order at 2.30 P.M., and introduced the President-elect, Dr. William A. Hammond, of New York.

DR. HAMMOND thanked the Association for the honor conferred upon him by electing him to the presidency. He thought the Association had great cause for congratulation for the work it had already done, in view of the indifference of many and the hostility of a few. Nowhere in the world was neurological science better cultivated than in this country, and he thought the Association had no reason to feel ashamed of the part it had taken in it. There was one point which he wished to call attention to, namely, the formation of local neurological societies throughout the country. These would be a great stimulus to special work and would serve as feeders to the Association.

The reading of the minutes of the last meeting being called for, it was moved by Dr. McBride that, as they had been printed and sent to each member for perusal, their reading should be dispensed with. Carried.

THE SECRETARY, DR. SEGUIN, reported that he had received a letter from Dr. Bartholow, expressing his regrets at not being able to be present. He also reported the receipt of several pamphlets and monographs from Dr. M. Bernhardt, associate member of the Association.

ELECTION OF OFFICERS.

The following officers were duly elected:

President.—R. T. Edes, M.D., of Boston.

Vice-President.—Dr. W. J. Morton, of New York.

Secretary and Treasurer.—Dr. E. C. Seguin, of New York.

Members of Council.—Dr. F. T. Miles, of Baltimore, and Dr. J. C. Shaw, of Brooklyn.

MISCELLANEOUS BUSINESS.

Dr. R. W. Amidon moved that the selection of the place for the next annual meeting be left to the discretion of the Council. Carried.

Upon motion of Dr. Shaw, Dr. Jewell's amendment to the constitution, viz.: "That all active members of the Association who shall remove from within the limits of the United States shall hereby become associate members should they so desire," was carried.

Dr. Seguin reported that only one essay had been handed in for the Hammond prize of five hundred dollars for the best account of the functions of the thalamus opticus, and that this essay was not considered of sufficient worth to merit the prize.

DR. HAMMOND announced that he would very gladly renew his offer for another year, and, if at the end of that time the prize was not awarded, he would pay it to the Association, with the understanding that it should form the basis of a fund to promote original investigation.

The first paper was by DR. R. W. AMIDON, of New York, entitled

THE MYOGRAPHY OF NERVE DEGENERATION IN ANIMALS AND IN MAN.

As a sphygmogram is a pulse-tracing, so a myogram is a muscle-tracing. By means of a mechanism, which was described, a muscle by its contraction moves a lever which makes a mark on the smoked paper of a revolving cylinder. It writes indelibly on paper the following facts: Quickness of muscular contraction and relaxation, amplitude of the muscular movement, and by means of some accessory apparatus, the quickness of contraction after the application of stimuli, and the effect of a continuance or a withdrawal of the same. Dr. Amidon first experimented upon healthy frogs, and afterwards upon those in whom the brain and spinal cord had been broken up to stop voluntary and reflex movements. The myographic studies undertaken in man were chiefly in cases of nerve injury or diseases which cause nerve degeneration and muscular atrophy. Dr. Amidon asserted that a careful perusal of the explanatory text which accompanied the plates exhibited, and a comparison of the different tracings among them, would reveal the following facts:

First, the identity as to form and relation of human and frog myograms in health.

Secondly, the great similarity of the pathological myograms in frogs and man.

Thirdly, the marked myographic changes where slight trophic disturbances affect human muscles.

Fourthly, the profound alterations in contour of myograms of muscles for a long time severed from the vitalizing power of their nerve centres.

DR. W. J. MORTON inquired if the author of the paper took into consideration the polar differences of the induced current.

DR. AMIDON replied that he did not think there were any polar differences.

DR. ROCKWELL asserted that the positive pole had a greater influence over the uterus than the negative pole, and that there must be a difference which ought to be taken into account in such delicate experiments as those alluded to in the paper.

The next paper was by DR. GEORGE M. BEARD, of New York, upon

THE SYMPTOMS OF SANITY AND THE DIAGNOSIS OF INSANITY.

DR. BEARD stated that the object of his paper was two-fold; *first*, to show what a sane man was. The normal retina, ear-drum, throat, and the normal condition of the parts of the body in general, have long been studied in order to enable us to know when disease attacks the body, but no one has studied the normal mind in such a way as to contrast it with an insane mind. The *second* object of his paper was to reconstruct the subject of insanity on the basis of evolution; to carry evolution into psychology. The law of evolution is the highest generalization the human mind has ever reached, and it is greater than gravity, and is revolutionizing the science of medicine. It originated, in its modern phase, in the brain of Herder, was developed by Goethe, and more recently still by Herbert Spencer, and Darwin, who has passed away. Dr. Beard said the *symptoms of sanity* were as follows: *first*, activity of the instinct of self-preservation; *second*, adaptation to environment; *third*, correspondence of character to age and station; *fourth*, rememberable consciousness. He who responds to all these tests is a sane man, no matter how sick he may be in body or mind. He who does not respond to these tests is an insane man, no matter how well he may be in body. Insanity is a disease in which mental responsibility is seriously impaired. There can be no insanity with perfect responsibility. The very essence of insanity is irresponsibility. Dr. Beard exhibited a diagram based upon evolution. It represented the most important nervous diseases in the form of a tree, each disease being a branch; one side being devoted to physical, the other to mental, diseases. On the

mental side were trance, hypochondria, mental hysteria, hystero-epilepsy, and insanity. On the physical side were chorea, neuralgia, neurasthenia, physical hysteria, epilepsy, and paralysis, beginning at the bottom and going to the top of the tree. Dr. Beard said that when mental disease attacked a person the symptoms began from above downward. The symptoms of *insanity* appeared in the following order, the later acquisitions first disappearing and then the earlier. There is, *first*, a decline in the manners, that is, minor morals, and then more extensive moral decline. *Second*, the power of originating thought. *Third*, the power of acquiring thought. *Fourth*, decline in memory of recent events. *Fifth*, decline in the memory of old events. There can be no insanity without moral decline. When a worm gnaws at the roots of a tree it is the blossoms that first begin to fade. When insanity attacks a mind it is the minor morals that are first destroyed. When an insane man wishes to kill, the chances are twenty-five to one he will kill himself; next to himself he will kill some relative or friend whom he dearly loves, as a wife or child. The third temptation is to kill some public character, any one who happens to be prominently before the public and excites the emotional nature. When any person without a confederate kills or attempts to kill the President of the United States or the Queen of England, the presumption is, a thousand to one, that he is crazy. Dr. Beard then went on to give, by means of his four tests of *sanity*, the differential diagnosis between fanaticism and insanity; between genius and insanity; between vice and insanity.

DR. J. J. PUTNAM, of Boston, read a paper entitled

CONTRIBUTIONS TO THE STUDY OF CENTRAL MYELITIS.

The paper consisted of a carefully written history of a hospital patient, together with an account of the post-mortem appearances. The history of the case illustrated that it was possible for such a patient to improve to a considerable extent, while at the same time there was an advance of the lesion. The case afforded an opportunity of referring to Dr. Ross's views, who thinks that the spinal cord should be divided into fundamental and accessory portions.

DR. MILES remarked that in cases of multiple neuritis the diagnosis is made upon loss of faradic contractility, non-implication of bladder and rectum retention, and loss of ankle clonus and tendon reflex. It was true that tendon reflexes were lost in poliomyelitis anterior, but here we should not expect pain.

DR. PUTNAM said that it was just this point which puzzled him. He was struck with the prominent symptom pain in the cases of poliomyelitis collected by Dr. Seguin. He thought it remained for future investigation to determine whether the peripheral nerves were first involved, and the affection of the anterior cornua was secondary to that. He had made no record of the faradic reaction.

DR. BEARD inquired if the observations were not in harmony with Dr. Ross's views.

DR. PUTNAM was not prepared to answer this question.

DR. WEBBER thought that the case reported supported Dr. Ross's views to a very considerable extent.

DR. E. C. SEGUIN, of New York, next reported a *Case of Injury to the Motor Area of the Brain.*

JUNE 21ST.—EVENING SESSION.

THE PRESIDENT, Dr. Hammond, called the Association to order at 8.30 P.M.

Dr. Miles was requested to take the Chair while DR. HAMMOND read the following paper

ON THE SO-CALLED FAMILY OR HEREDITARY FORM OF LOCOMOTOR ATAXIA.

Twenty years ago, when doubt existed relative to the seat and nature of the lesion constituting the disease now generally known as locomotor ataxia, Friedreich, of Heidelberg, published an elaborate essay, of which the title, "On Degenerative Atrophy of the Posterior Columns of the Spinal Cord," indicated the view which he entertained of the morbid anatomy. All writers had, so far as Dr. Hammond knew, accepted without question, Friedreich's view of their character, while no one had thought it worth their while to study them in the light of our present knowledge. No neurologist of the present day, after a full consideration of these cases, would regard them as instances of locomotor ataxia. In every one of Friedreich's cases the first symptom observed was weakness of the lower extremity, which gradually extended so as to involve the upper extremities. We find also that in no single case at any period of its course was there the slightest loss of cutaneous or muscular sensibility. In no case was there any derangement of the excretion of urine. Dr. Hammond thought that when, as in Friedreich's cases, the lancinating pains are not invariably met with, in fact, being very rare, when there is no swaying of the body on closure of the eyes, when the inevitable result is that the morbid process extends upwards, that the speech becomes affected, that the pupils are always equal, not contracted, and reacting perfectly to light, we have an *ensemble* of symptoms which are absolutely incompatible with the idea of primary degeneration in any part of the posterior columns of the cord.

Dr. Hammond reported in full the histories of twelve cases similar to those of Friedreich's which had come under his own observation. These examples of the disease all occurred in children. All were healthy up to the time of the appearance of the paralysis. Parents usually healthy. The disease begins with weakness in the lower extremities and then gradually advances upward with nearly complete freedom from pain. In all the speech was involved in a peculiar manner. The pupils were equal in size and normal in reaction. The gait of these children was altogether different from that of ataxics. Instead of the feet being put down with a jerk and in two distinct movements, they were moved exactly like those of a drunken man when he attempts to walk. For these reasons Dr. Hammond could not consider the cases in question to be instances of locomotor ataxia or sclerosis of the columns of Burdach. These columns might in some cases be affected, but in such it was clearly a secondary phenomenon.

In the absence of sufficient post-mortem evidence, Dr. Hammond hesitated to assign a locality to the lesion which constitutes the pathological entity of the cases to which he had referred. He was inclined to think, however, that its primary seat is the medulla oblongata. This opinion was based on a careful consideration of the symptoms.

DR. SEGUIN had seen at least a dozen cases of this kind of which he had notes. They had occurred in families, varying from one to three. He had always considered Friedreich's cases as examples of disseminated sclerosis of the spinal cord. The same was true of Carre's case. Nystagmus, imperfection of speech, ataxia and yet absence of pains, anæsthesia and the peculiar iris symptom which we expect in post-spinal sclerosis, were characteristic symptoms of these cases.

DRS. ROCKWELL and MORTON called to mind similar cases to those reported by Dr. Hammond.

DR. HAMMOND said the objection to considering these as cases of disseminated sclerosis was that tremor was absent upon attempting voluntary motion.

Dr. H. M. Bannister, of Chicago, read a

NOTE ON BROMIDE MANIA, AND THE SUPPOSED COMPENSATORY ACTION OF EPILEPTIC ATTACKS.

Dr. Bannister referred to the fact that Dr. Stark had committed himself to the view that the maniacal excitement was due to the suppression of the fits rather than to the bromide. On the other hand, Dr. Hammond had noticed cases, which, not being epileptics, could not be accounted for on the theory of Dr. Stark. He then gave the history of the case in which the fits were suppressed by bromide with the result of producing maniacal excitement, which subsided at the discontinuance of the medicine. It was found that the attacks could be completely controlled, and the general condition of the patient much improved by the administration of a one per cent. solution of nitro-glycerine. He thought the case conclusive so far as one case could be.

Dr. Mills considered it a very important matter in discussing this question to clearly distinguish cases of hystero-epilepsy from those of epilepsy in regard to the action of bromide. There was a status hystero-epilepsy as well as an epileptic status. Bromides acted badly in hystero-epilepsy. With reference to the occurrence of mental disturbances in epileptics by the use of bromide, Dr. Mills spoke of three distinct conditions, namely, a pre-paroxysmal condition, a post-paroxysmal condition, and the substitution of the epileptic attack by a maniacal attack. Only in a very few instances had he seen bad effects from the use of this remedy.

Dr. Bannister said there was no suspicion of hystero-epilepsy in the case reported.

Dr. E. C. Seguin read a paper entitled

A CONTRIBUTION TO THE CLINICAL STUDY OF ARSENICAL MYELITIS.

The three cases reported were rare sequels of Paris-green poisoning. A summary statement of them may be made to the effect that they all presented evidences of slight sub-acute diffuse myelitis, more distributed in the anterior cornua. In case I., the symptoms were more purely those of poliomyelitis. In all cases, the symptoms of myelitis followed within a week after the ingestion of the poison. Whether the myelitis was caused by the direct action of the arsenite of copper upon the spinal cord, or whether it arose as a result of irritation of the nerves of the stomach and intestines, was the important question which he wished discussed by the Association.

Dr. Hammond inquired if the poisoning was due to the copper or the arsenic.

Dr. Seguin's impression was that the effects reported were those of arsenic.

Dr. Amidon thought the cases reported were very similar to those of spinal-cord paralysis following diphtheria, and it had always seemed to him that their pathology must be somewhat similar.

Dr. Seguin remarked that most of his cases of diphtheritic paralysis had shown a toxic stage previous to the paralytic stage.

Dr. Miles saw no reason why the cases reported should not be looked upon as examples of general diffuse neuritis.

Dr. Seguin thought that the irritation of the nerves of the mucous membrane might have led to the production of myelitis in a similar manner to its production by cold after exposure.

Dr. Hammond stated that eighteen months ago he had a case similar to those reported by Dr. Seguin, in which the poisoning was clearly due to copper: the ammonio-sulphate was prescribed, with directions to take one-twelfth of a grain; instead of taking the number of drops ordered, the patient took an equal number of teaspoonfuls. Paralysis of all the muscles, except those of respiration, followed, and continued for seventy-two or eighty hours, when their functions were gradually regained.

Dr. W. J. Morton, of New York, read the next paper, entitled

MECHANICAL VIBRATION FOR THE RELIEF OF PAIN—A NEW PERCUTEUR.

Next to the anæsthetics and narcotics, counter-irritation has long held a prominent place in the treatment of pain. The general law which governs the relief of pain by counter-irritation remained unformulated until within a year, when M. Brown-Séquard, after careful experimentation, announced the general principle that general and local anæsthesia could be produced in the lower animals by applying to the peripheral nerve distribution a strong counter-irritant, and that this anæsthesia was explicable on the theory of inhibitory action. Within a few years delicate methods of affecting the sensitive peripheral network of nerves have been brought forward under the general term, æsthesiogenic agents. This work has emanated from the clinic of Professor Charcot, and has been elucidated mainly by Dr. Vigauraux. Hypothetically, all forms of force display themselves in vibrations; heat, light, sound. Nerve force, whatever its nature, is probably vibratile. There is a form of vibration which is communicated directly from the vibrating agency to the part to be treated. This may properly be called mechanical vibration, and it was that to which Dr. Morton wished particularly to call attention. To Dr. Mortimer Granville, of London, is due priority of treatment by this method.

Dr. Morton exhibited a new percuteur, in the construction of which he aimed at a mechanism which would have a more powerful stroke than Granville's clock-work percuteur and the dental hammer, and at the same time give less trouble than the tuning-fork percuteur, which required the use of a small galvanic battery. His instrument involves the idea of applying the vibrating rod directly to revolving hammers actuated by a crank movement.

Granville's hypothesis of the action of percuteurs is that sharp pains are represented by very rapid vibrations, and that "boring" and "grinding" pains are represented by comparatively slow vibrations. Consequently in order to break up either one or the other forms of pain, it is necessary "to set up a new set of vibrations, which shall interrupt or change the morbid set by introducing discord."

June 22d.—Afternoon Session.

Dr. James J. Putnam, of Boston, exhibited two instruments. The first was a little *microtome*, to be held in the hand and used for the purpose of making sections of the spinal cord. The instrument avoided the necessity of imbedding the specimen. The second instrument was a modification of Pond's *sphygmograph*, the main advantage of which was that it provided the means of regulating the pressure on the pulse.

Dr. S. G. Webber, of Boston, read a paper

ON LEAD-PARALYSIS,

which was limited to a brief review of the theories of the pathogenesis of lead-paralysis, and secondly, to calling attention to some unusual forms in which lead-poisoning may show itself, simulating more serious lesions. There are two views now most prevalent in regard to the seat of the lesion in lead-paralysis. Some authors consider the central nervous system, the spinal cord and brain, to be the part primarily affected. Another view is that the primary seat of disease is in the nerves. The evidence brought forward by some

observers would seem to be conclusive that the paralysis does not depend upon a central lesion; but objection has been raised that it requires only a very limited lesion in the cord to give rise to the symptoms observed, and it is said that the examinations have not been complete.

Dr. Webber asserted that as yet we have no proof that the higher centres, as the brain or cord, can cause lesion of different parts of the nervous system, as cord or nerve, without a continuous track of degenerated tissue intervening. He thought, however, that in lead-paralysis the mass of evidence derived from pathological anatomy would show that the disease is primarily a neuritis, unless the origin by separate and independent centres is accepted as the true explanation. The fact that many cases of lead-paralysis recover is also in favor of the peripheral rather than the central origin of the disease. Another fact which he considered important in furtherance of this idea was that in every case in which he had questioned the patient there had been pain, more or less severe, or soreness, or a tingling sensation preceding the motor disturbances. Dr. Webber desired to emphasize the peculiarity that in cases of lead-poisoning there were symptoms present resembling those of myelitis. He thought it very important to examine the urine for lead after the administration of iodide of potassium.

DR. PUTNAM remarked that he had seen two cases of lead-paralysis that would never have been considered as such, one resembling lateral sclerosis and the other myelitis exanæmia.

DR. SEGUIN mentioned a case of lead-paralysis in which the symptoms were indentical with poliomyelitis. Lead was found in the urine. This was one of a number of cases in which he would defy any neurologist to make a diagnosis between poliomyelitis and lead-paralysis.

DR. BIRDSALL thought that when we consider how often this disease does not assume a serious form it would not be improbable that changes existed in the cord which were not sufficient to produce impairment. As to the electrical reactions, he had found them present to a very limited extent. The true reversal of the galvanic reaction formula is not as frequent as in myelitis of the anterior horns. He thought that in a certain number of cases there would be found present functional impairment without discoverable lesion of the spinal cord.

DR. V. P. GIBNEY testified to having frequently observed severe pain in poliomyelitis anterior. He had seen many such cases.

DR. HAMMOND remarked that he had long entertained the opinion that the original lesion was central, but much experience had convinced him that the original lesion was in the nerves. The paralysis affects those parts to which the poison is directly applied.

DR. EDES thought that the poison usually entered the system through the lungs or alimentary canal, and that the paralysis showed itself in the muscles which we use the most.

DR. CHARLES K. MILLS, of Philadelphia, read a paper entitled

CLINICAL NOTES ON TWELVE CASES OF BRAIN TUMOR, CHIEFLY WITH REFERENCE TO DIAGNOSIS.

The notes presented were on twelve cases of intracranial tumor in which the clinical examination and the autopsies had been made by Dr. Mills. They were arranged in tabular form, in one column giving a very much condensed clinical history and in another the gross post-mortem appearances and the results of microscopical examination. The facts thus tabulated were then summarized and conclusions drawn.

Headache usually described as present, pain of considerable severity with exacerbations of great violence. In several instances the patients complained of the pain being greatest in the region of the head nearest the seat of the growth. Percussion of the head elicited or intensified pain in the cranial region beneath which the lesion was localized. Vomiting was a symptom in eight of the twelve cases. In a case of tumor of the cerebellum, so located as to cause irritation of the floor of the fourth ventricle, vomiting was persistent. In most of the cases the vomiting was ascribed to irritation of the nerves of the cerebral membranes, the observer agreeing with Ferrier with reference to this point. Vertigo was noticed in ten cases, most marked in two cases of cerebellar tumor. Dr. Mills believed that the general diagnosis of the existence of intracranial tumors could be made with greater certainty than that of any other serious encephalic disease.

DR. PUTNAM inquired if the author of the paper distinguished sharply between choked disk and neuritis.

DR. ROCKWELL mentioned a case of a patient who first suffered from hysterical attacks followed by epileptiform attacks. Headache was present from the beginning, and finally became excruciating in character. The symptoms were such as to lead him to the suspicion of brain tumor, but upon post-mortem examination no such lesion was found, there being present only cloudiness of the arachnoid.

DR. MILLS considered it important in the diagnosis of brain tumor that their character be taken into consideration, that is, whether in their growth tissue was destroyed or the parts pushed aside; whether it was a destructive or pressure lesion.

DR. SEGUIN expressed his pleasure of the views entertained by the author of the paper in regard to localization of brain tumors. Though pain was present in many cases, it had so happened that in most of the well-defined cases of sarcoma that had come under his observation there was no headache. In only one case of cerebral tumor had he observed choked disk. All of his cases of basal tumor had choked disks. In one case of sarcoma within the medulla oblongata, choked disk was present.

DR. MILLS, in reply to the first question asked, would say that, in his opinion, we have, according to the position and character of the tumor, choked disk, either from its mechanical cause, or from the seat of the lesion. He was inclined to favor the so-called lymph-space theory in regard to the production of choked disk.

A CASE OF POST-PARALYTIC CHOREA, WITH REMARKS ON THE TREATMENT OF CHOREIC SYMPTOMS IN GENERAL.

DR A. D. ROCKWELL, of New York, read a paper with the above title. The case reported was one of long standing. The patient could not carry a glass of water to his mouth without spilling. The speech was somewhat affected, and the right pupil dilated. The treatment in this severe and unpromising case was threefold. First, ether spray to the spine; second, fluid extract of conium internally; third, central galvanization. Under these influences, the boy immediately and steadily improved, and in ten weeks was discharged cured. The reader was inclined to regard the ether spray in these chronic cases as of but little value. Conium he had more confidence in. In regard to the value of electrical applications, Dr. Rockwell's views were the same now as he had expressed a dozen years ago, and, with his added experience, he claimed the same position for it in its relation to this disease as at that time.

DR. MORTON had tried strychnia, arsenic, and electricity in the treatment of chorea, and had become satisfied that any severe treatment would cure. The same good effects which Dr. Rockwell had obtained from the administration of conium, he would expect

from other remedies administered in large doses. He thought the principle of treatment in chorea was one of surprise.

DR. EDES considered the dose of conium as put down in the books absurdly small. He thought no effects could be expected from five-minim doses. He commenced with fifteen-minim doses, which were increased until the physiological effects were produced.

DR. SEGUIN testified to giving conium in teaspoonful doses, using Squibb's fluid extract. He gave from ten to fifteen minims at the first dose.

DR. HAMMOND gave from fifteen- to thirty-minim doses to children five and ten years of age; to adults he had given sixty-minim doses.

DR. ROCKWELL stated that he commenced with five-drop doses, and, if necessary, increased to twenty-five. The cases of chorea recorded by him were of long standing.

DR. GRAEME M. HAMMOND reported

A CASE OF ATHETOSIS CURED BY NERVE-STRETCHING.

The results of nerve-stretching in spinal and cerebral diseases have been, as a rule, very unsatisfactory in nearly all cases where the disease had been traced to any organic change in the central nervous system. Athetosis, according to the post-mortem examinations, comes within this classification, and up to the present time, after almost all kinds of experiments have repeatedly failed, it is universally looked upon as an incurable disease. So far as he was aware, only one operation had been performed for its relief prior to his own. This was done by Dr. W. J. Morton. Dr. W. A. Hammond, on May 23, 1882, sent to the author of the paper his original case of athetosis, first seen in the year 1869, recommending that one or more of the nerves in the arm should be stretched. On May 27th, the median nerve in the middle of the arm at the inner border of the biceps muscle was exposed and slightly stretched, making traction in both an upward and downward direction. Immediately after the operation was performed, and as soon as the patient had recovered from the influence of the anæsthetic, he was able to extend his fingers and to retain them in that position with the greatest ease, and found no difficulty in placing them in any position he desired for as long a time as he wished. The pain in the arm was entirely relieved, but the pain in the ring and middle finger had increased, which was subsequently relieved by static and faradic electricity. The movements and pain in the foot had also ceased, and have not returned up to the date of reading the paper. The frequency and force of the epileptic paroxysms from which the patient suffered, occurring as often as six or seven times a week, have been much reduced, the patient having had but one attack since the operation.

PRESIDENT HAMMOND remarked that the most astonishing feature of the case recorded was that the movement and pain in the foot had ceased, and that the epileptic attacks had been almost abolished.

There being no further discussion, the President stated that there would be no evening session, and in lieu thereof extended a cordial invitation to the members of the Association to a reception at his house.

JUNE 23D.—AFTERNOON SESSION.

The first business was the reading of a paper by DR. V. P. GIBNEY, of New York, on

A CASE OF SWIFT AND ONE OF SLOW COMPRESSION OF THE UPPER CERVICAL CORD FROM DISPLACED ODONTOID PROCESS; WITH SPECIMENS.

The detailed histories of these two very interesting cases were presented together with a description of pathological findings in each. The post-mortem appearances were those usually found in compression myelitis. The principal changes at the point of compression, which involved the white matter, were in those portions which lie next to the posterior horn in the lateral columns extending out into the portions representing the true cross-pyramidal fibres.

DR. MORTON referred to an extremely interesting specimen in the hands of Prof. William Darling, of fracture of the odontoid process and atlas. The canal was reduced to the size of one's little finger. The patient must have survived quite a number of months, as there was perfect union of the fragments. He referred to a case, which he had reported, of dislocation of the fifth cervical vertebra, and which he had reduced by suspending the patient by the neck and chin.

NEW MEMBERS.

The order of business was suspended and the Council reported, through Dr. Seguin, favorably upon and recommended for active membership Dr. C. L. Dana, of New York. The Council reported favorably upon and recommended for associate membership Dr. Mierzenjewski, of St. Petersburg, and Dr. Argent Ollivier, of Paris. These gentlemen were duly elected.

Dr. Edes was requested to take the chair, while DR. WILLIAM A. HAMMOND read his paper on

THE DISEASE OF THE SCYTHIANS—MORBUS FEMINARUM, AND THE ANALOGOUS CONDITIONS.

From a very early period the idea has existed that the male inhabitants of the Caucasus are subject to a peculiar disease, the chief characteristics of which are the loss of the physiological and moral attributes of man, the supervention of impotence, the disappearance of the beard, the atrophy of the penis and testicles, and eventually the implication of the mind to such an extent that the subjects believe themselves to be women, clothe themselves like women and adopt the manner, customs, and occupations of the female sex. A very exhaustive historical sketch of this condition was given by the author of the paper. Dr. Hammond related his observations on the Pueblo Indians, who have among their number examples of an allied condition brought about intentionally to a very great extent by horseback-riding and masturbation. The case of Edwin Hyde Lord Cornbury, Governor of New York, during the reign of Queen Anne, adduced by Dr. Spitzka, was referred to as a person whose greatest pleasure was to dress himself as a woman, and New York frequently saw its Governor, the Commander of the Colonial troops and a scion of the royal stock, promenading the walls of the little fort in female attire with all the coquetry of a woman, and all the gestures of a courtezan.

DR. F. T. MILES, of Baltimore, exhibited some morbid specimens, and presented a brief history of a

CASE OF HEMORRHAGE INTO THE PONS; DEATH ELEVEN MONTHS AFTER.

There was hemorrhage into the lower part of the pons on the left side, in the median line near the floor of the fourth ventricle, about the position of the acoustic striæ.

DR. C. L. DANA, of New York, read a paper upon

THE MECHANICAL EFFECTS OF NERVE-STRETCHING UPON THE SPINAL CORD.

The spinal cord hangs rather loosely in its canal. It changes its position in the different movements of the trunk. The question in nerve-stretching, therefore, is essentially not whether the cord moves, but whether it is stretched. The spinal cord is quite firmly connected with the dura mater. This is fastened to the

borders of the foramen magnum; below it extends over the nerve roots into the inter-vertebral canals, and is continuous with the nerve sheaths. In pulling on the sciatic nerve the traction comes on the cord and dura together, but chiefly on the latter. Details of experiments upon the human cadaver were given, which proved possibilities of stretching the spinal cord.

The clinical evidence that stretching the sciatic nerve moves the spinal cord is confined chiefly to the cases in which the cutting operation is done. In the great majority of cases of nerve-stretching no evidence of any mechanical violence to the cord is shown. The subject of subcutaneous nerve-stretching was referred to at some length. The evidence that any central change is produced by this means was considered very slight. Cases in which subcutaneous nerve-stretching have been used were cited. From his studies, Dr. Dana formulated the conclusions:

(a.) As regards the cutting operation: (1) traction upon the sciatic nerve of the cadaver in a majority of cases stretches the spinal cord; (2) this stretching is greatest at the lower part, amounting to 2 to 3 mm. with a very powerful pull; (3) the movement is distributed over the yielding cord and only in a minority of cases does it reach the medulla. The medulla then moves very slightly, less than 3 mm.; (4) when the cord is not moved it is due probably to the tight adhesion of the sheath to the nerve and of that to the surrounding tissues, especially in the inter-vertebral canal; (5) traction upon the nerve and sheath, if it reaches the spinal canal, acts chiefly upon the dura; (6) it may be legitimately inferred that what happens in the cadaver occurs also in the living subject.

(b.) As regards subcutaneous nerve-stretching: (1) on the cadaver this is a powerful means of moving the cord; (2) in the living subject it is very doubtful if subcutaneous nerve-stretching affects the cord mechanically at all. The clinical evidence is very meagre; anatomical evidence can not be obtained.

DR. MORTON testified to the carefulness with which the experiments alluded to in the paper were performed. He thought the subcutaneous method would be more generally used than the cutting operation.

DR. HAMMOND had never had any doubts but what the spinal cord was stretched by the subcutaneous method.

DR. R. T. EDES, of Boston, read a paper on so-called

SPINAL CONCUSSION.

The paper was intended to point out the occurrence, in a certain number of cases of somewhat obscure pathology, of a definite and well-known lesion.

He had not been able to find any statement of the frequent occurrence of this lesion, or its symptoms, among the very various and vague sequelæ of spinal concussion. Several cases had occurred in his hospital service, in which the clinical evidence of degeneration of the postero-lateral columns of the cord had been very clear, and where the causation had seemed to be a severe shock to the spinal column, producing no appreciable osseous or ligamentous lesion. Brief histories of four cases, with remarks, were given.

DR. W. J. MORTON, of New York, read a paper on

A YEAR'S PROGRESS IN MEDICAL ELECTRO-THERAPEUTICS BY STATICAL ELECTRICITY.

The author first gave a brief historical sketch. Then followed an enumeration of the progressive steps which had been taken, under the headings: 1. Machines. 2. Electrodes. 3. A new current, introduced by the author. 4. Therapeutic progress.

Under the latter heading, Dr. Morton stated that, as a curative form of treatment, he had more confidence in it than formerly, and thought that static electricity was fully the equal, if not the superior, of galvanism and faradism. He divided the cures by electricity into four classes:

1. Effected, we know not how.
2. Effected by nerve and muscle stimulation.
3. Effected by molecular change, and consequent alteration of nutrition, by direct and local electrization.
4. Effected by reflex and by inhibitory action.

It was in the third class that he believed statical electricity superior to any other form. Dr. Morton then proceeded to specify the ailments which he believed were particularly amenable to static electricity. In hysteria he claimed for it an almost specific influence.

DR. ROCKWELL remarked that his experience with static electricity had, on the whole, been very satisfactory; but he did not think it was possible to consider it as valuable as the other two forms. The dynamic form had a much wider range of usefulness. There were some cases benefited more by static than by dynamic electricity.

DR. DANA had made some use of static electricity within the past six months, and found it very useful. He had interested himself more particularly with its tonic effects, and had found it of great value in neurasthenia and chronic rheumatic articular affections.

DR. AMIDON had never done anything with static electricity, but considered it of little value except as a counter-irritant and slight tonic. It was a decided excitant of the imagination.

DR. G. M. HAMMOND reported beneficial results from the use of static electricity in cases of progressive muscular atrophy.

THE SECRETARY read a letter from Dr. J. J. Mason, of Newport R. I., which was accompanied by photographs of the nuclei in the nerve cells of *Ignana tuberculata*. He had found no gigantic cells in the nucleus oculomotorious, or trochlians.

DR. W. R. BIRDSALL, of New York, read a paper on

THE SLEEPING DISEASE OF AFRICA.

The disease was ushered in by a chill and headache. The patient loses his spirits, is disinclined to do anything, has a staggering gait, suffused eyes, and dilated pupils. This part of the disease is called "ozyone." Ozyone is said to be almost identical with ordinary nasal catarrh. The patient may remain in this condition for from two months to a year before decided somnific symptoms present themselves. When this stage is reached, the patient does little else but sleep and eat. Appetite, even at the best, is remarkable. As soon as patient has finished his meal he immediately retires until the next is ready. During sleep the pupils are normal, as are also the pulse, temperature, and respiration. The duration of this stage, which is called by the natives "*Nkanli y'anty âvinlâ*," is said to be about two months, at the end of which time the patient quietly dies, without convulsions or any other prominent symptom.

DR. SEGUIN reported a case similar to those described in the paper which had come under his notice a few years previous.

A very interesting paper on *Vertebral Cancer and Paraplegia* was read by DR. E. C. SEGUIN.

DR. H. D. SCHMIDT'S (New Orleans) paper on "*A Case of Tumor in the Fourth Ventricle of the Brain, unaccompanied by Special Symptoms*," was read by title.

There being no further business, upon motion, the Association adjourned until the third Wednesday in June, 1883, the place of meeting to be hereafter determined by the Council.

AMERICAN LARYNGOLOGICAL ASSOCIATION.

Fourth Annual Congress, held at Boston, June 12, 13, and 14, 1882.

(Specially reported for THE MEDICAL NEWS.)

MONDAY, JUNE 12.—The Fourth Annual Congress of the American Laryngological Association convened at the Hall of the Boston Medical Library Association, the PRESIDENT, DR. FREDERICK J. KNIGHT, in the chair.

THE ADDRESS OF WELCOME

was made by DR. S. W. LANGMAID, of the Committee of Arrangements. In bidding the Fellows welcome to the meeting, he called attention to the position the Association had already attained among medical organizations, and the high character of its published proceedings. The pleasant task of entertaining the Association had been rendered easier by the fact that the Fellows were, in virtue of the abundance of provision upon the programme, hosts as well as guests. The number of papers promised gave evidence of great activity and interest, which was confirmed by the attendance upon the Congress. Owing to the amount of business before the meeting, he would not extend his remarks, but conclude by extending to the Association, on behalf of the Committee of Arrangements, a cordial welcome to Boston.

DR. FREDERICK J. KNIGHT read the

PRESIDENT'S ANNUAL ADDRESS,

in which he discussed the position of laryngology among specialties, recommended more attention to the subject by medical schools; considered the details of clinical instruction and its importance as part of the under-graduate course in colleges. The essential necessity of higher medical education was dwelt upon, and the cultivation of a more healthy public sentiment was considered a part of the physician's duty, and for which he should lend his influence. The need of having our medical teachers' incomes entirely independent of the size of their classes was dwelt upon, and the endowment of competent colleges recommended.

The change of place of meeting from Niagara to Boston was explained; and the advantages of holding meetings in large cities, where hospitals and dispensaries exist, over watering places were pointed out. In conclusion he recommended that all future meetings should be held on the third Monday of June, and at a distance not greater than one night's journey from New York City, inasmuch as a large number of the Fellows live in that city.

PROF. ELSBERG read his paper on *Paralysis of the Laryngeal Muscles*, which he illustrated by diagrams demonstrating the results of the forms of paralysis resulting from paralysis of each of the five muscles of the larynx. These laryngeal images also showed different degrees of paralysis, or paralysis of only a part of a muscle, both uni- and bi-lateral. The complication of spasm with paralysis was also discussed, and the resulting distortion of the glottis explained. Catherization was urged to be sometimes a valuable substitute for tracheotomy. The paper was discussed by Drs. Bosworth, Seiler, Roe, Hartman, and Morgan.

DR. CARL SEILER read a paper forwarded by DR. W. C. GLASGOW, of St. Louis, who was unable to attend, entitled *Laryngeal Asthma*, which called attention to bronchial spasm due to laryngeal disease, and cited a number of cases in illustration. The attacks of asthma produced by reflex irritation in the bronchi are well recognized, but when pathological changes cannot be demonstrated in the lungs, but are found in the larynx, and when local treatment of the latter organ removes the diseases, it is evidence that laryngeal disease must be classed as one of the causes of reflex bronchial spasm, and a laryngoscopic examination may guide a treatment that would lead to cure in cases otherwise intractable.

DR. ROBINSON objected to the elevation of an accident of a disease into a special form of disease. Asthma is due to many causes, a peculiar neurotic element present, and brought on by irritation of various parts of the air passages other than the larynx. Discussed also by Drs. Jarvis and Seiler.

Dr. J. R. FRENCH, of Brooklyn, exhibited some photographs of the interior of the larynx taken by means of the mirror, and explained the process of photographing the living larynx.

The Association went into business session at 12.30 P. M., for the election of Fellows and nomination for officers.

Drs. Langmaid, Shurley, and Lincoln were appointed as a *Nominating Committee*.

Drs. Elsberg and Morgan, *Auditing Committee*.

Drs. Seiler and Bosworth were appointed *Tellers*.

The following *New Fellows* were declared to be elected on recommendation of the Council: Drs. S. H. Chapman, of New Haven, Ct.; Thos. Amory De Blois, of Boston; F. H. Hooper, of Boston; Frank L. Ives, of New York; and D. N. Rankin, of Alleghany, Pa.

AFTERNOON SESSION.—The Association met again at three o'clock; when DR. D. BRYSON DELAVAN read an interesting essay *On the Question of Hypertrophy of the Osseous Structure of the Turbinated Bones, Practically Considered*, in which the occurrence of the enlargement of the middle turbinated bone particularly, as a cause of deflection of the septum, and the treatment of the resulting stenosis by removal of part of the hypertrophied bony structure, and subsequent straightening of the canal was recommended. A general discussion followed.

DR. FRANK H. BOSWORTH, by appointment, opened the discussion upon *Ozæna, its Pathology and Treatment*, by pointing out the different causes of offensive secretions from the nose, which he classed under four heads, (1.) Syphilitic ulceration, (2.) Scrofulous ulceration, (3.) Foreign body with retained secretion, (4) Rhinitis in which there is adherent crusts. He advocated the disuse of the word ozœna as unscientific. In the treatment strict cleanliness, removal of obstructions to outlet of secretions, and stimulating applications in cases of rhinitis, were recommended. In the first two forms, constitutional treatment is also required.

An interesting discussion on the paper took place, during which DR. THOMAS F. RUMBOLD took occasion to exhibit his catheter spray douche for cleansing the nares.

In the evening the Fellows of the Association attended a reception at the house of the President, Dr. F. J. Knight, where they were invited to meet the Faculty of Harvard University, the Members of the Hospital Staffs of the Massachusetts General and City Hospitals, and some members of the Massachusetts State Medical Society, then holding its one hundred and first annual session in this city.

TUESDAY, JUNE 13.—At the beginning of the morning session an hour was devoted to the

BUSINESS MEETING.

The Secretary presented the minutes of the last annual meeting which had been already published and distributed, and also of two meetings of the Judicial Council; the Treasurer's report, exhibiting a balance of $117.51, was audited by Drs. Elsberg and Morgan, and found correct.

The Nominating Committee presented the following report:

Place of Meeting, New York City on the third Monday in May, 1883.

OFFICERS.

President, G. M. LEFFERTS, M.D., of New York.

Vice-Presidents, DR. CARL SEILER, of Philadelphia; E. F. INGALS, of Chicago.

Secretary and Treasurer, DR. D. B. DELAVAN, of New York.

Librarian, DR. F. H. BOSWORTH.

Council, MORRIS J. ASCH.

Miscellaneous Business.—The PUBLICATION COMMITTEE reported the publication of the last volume of Transactions, and announced that the first volume had also been completed, and the bill was ordered to be paid.

Dr. Knight presented a provisional report of the Committee on Nomenclature, on behalf of Dr. J. Solis Cohen. On motion, copies were distributed for consideration by the Fellows for another year.

The Librarian, Dr. Bosworth, announced a number of additions to the library.

A report from the delegates to the International Medical Congress, Dr. Cohen, chairman, was read and filed.

Dr. L. Elsberg, of a committee appointed for the purpose, read an obituary notice of Dr. F. H. Davis, which was accepted, and ordered to be placed upon the minutes.

Dr. Bosworth representing the committee on diplomas for foreign members, presented a draught which was accepted, and the committee authorized to have the plate engraved at once, and also in connection with the judicial council to prepare a suitable seal to be affixed to such diplomas.

The action of the Council in changing the place of meeting from Niagara Falls to Boston, was, after considerable discussion, approved.

Dr. Elsberg, on behalf of the publishers of the *Archives of Laryngology*, offered to publish the transactions on the same terms as before, which was, on motion, accepted.

It was resolved that discussion should be postponed until the three papers on the programme for the morning session were read.

E. FLETCHER INGALS, M.D., of Chicago, read a paper on *Deflection of the Septum Narium.*

DR. WM. C. JARVIS, of New York, read a paper on

A NEW OPERATION FOR THE REMOVAL OF THE DEVIATED SEPTUM IN NASAL CATARRH.

The operation was in many respects similar to the now popular one devised by him for the removal of turbinated hypertrophies. He referred to Dr. W. Adams as one of the first surgeons to successfully overcome by an ingenious operation distortion of the nasal septum. The various septum perforators and nasal fracture forceps, now in general use, were shown to be the result of the stimulus received from the invention of Adams' well-known instrument.

Although marked deformities of the nose had been remedied by these operations, they were, nevertheless, open to objection. Slight but pathologically important deviations of the triangular cartilage of the septum, were not remediable by Adams' operation, but could be easily remedied by his own. He strongly condemned the practice of perforating the septum to obtain a delusive bilateral nasal respiration, by creating an oblique air-current from the open nostril. Attention was directed to the life-long discomfort caused by the collection and inspissation of mucus about the edges of these unnatural openings, a condition observed in patients having ulcerative perforation of the septum narium. He divided deviations of the nasal septum into three varieties, osseous, cartilaginous, and hypertrophic. These three varieties occurred in two forms, localized and general. The first form included such conditions as dislocation of the cartilage of the columna, cartilaginous spurs and ridges in the triangular cartilage, and hypertrophy of the mucous membrane over the vomer, ethmoid, columna nasi, and osseous spurs. The second division included extensive deflection of the cartilaginous and osseous septum.

He demonstrated the rare occurrence of osseous spurs mentioned by some authors as of such common occurrence, by reference to Professor Bosworth's large throat clinic, at Bellevue Hospital. Three different instruments were employed by him in operating, namely: A wire écraseur, transfixion needle, and septum scissors. The écraseur was identical with the one already presented by him, and so familiar to the medical profession. The tissue forming the most prominent part of the deviated septum was pierced at its base by means of the transfixion needle, and the wire loop carried over the point projecting into the nostril. On drawing the wire home all the cartilaginous or hypertrophied tissue outside the needle's shaft was severed from its connection with the nasal septum. The needle acted somewhat like a director. The slow traction employed to accomplish a bloodless operation, also insured the smallest amount of pain.

Localized cartilaginous projections could be removed at a single sitting. Marked general deviations required several operations. The fine steel wire employed would sever the densest cartilage without fracturing. Small ridges of cartilage were seized and snipped off by a peculiar beaked scissors having an angular shank. Its shape facilitated inspection of the part while operating. Sufficient space could be obtained in partly osseous deviations of the septum by removing the soft tissues to restore nasal respiration and relieve contact. An ample opening could be obtained in a nostril rendered imperforate by a combined osseous and cartilaginous deviation by simply excising the soft septum tissues and portions of the turbinated structure lying opposite. Imperforate nostrils were perforated by employing a needle having its point almost at a right angle with the shaft. Successive portions of the obstruction were transfixed and snared off until a free opening was established.

Attention was called to the part played by the hypertrophied mucous membrane overlying the septum. In nasal catarrh many of the so-called cases of deviated septum were really hypertrophies of the overlying mucous membrane, produced by the irritation of tumefied or hypertrophied turbinated tissues lying opposite. These obstructions not only impeded respiration, but acted as irritants, and, by distorting the nasal gutter, prevented the easy efflux of the nasal mucus; the mucus thus retained, by becoming inspissated, contributed to the stenosis and acted as an additional irritant. The recognized fact that marked distortion of the nasal septum was, as a rule, unaccompanied with external deformity, was favorable to his method of operating.

A clean surface was essential to success in restoring the internal symmetry of a distorted nostril. One drop of blood was sometimes sufficient to veil the field of operation and prevent immediate progress. Hence the failure of cutting instruments, whose intelligent use was dependent upon careful ocular inspection. As the manipulation of the transfixion needle and placing of the wire loop was attended by no hemorrhage, a clear view and precise movement were invariably secured, and, as might be expected, the results were definite, satisfactory, and sure.

Specimens of septum tissues removed by his method were exhibited, and his remarks were well illustrated by drawings enlarged from careful sketches. No exceptions were taken to his claims.

E. L. SHURLEY, M.D., of Detroit, read a paper on

Lupoid Ulceration of the Nasal Septum. In the discussion the pathology of nasal stenosis due to deviated septum was considered, and the several operations for its correction compared. Preference appeared to be given to the method of Dr. Jarvis with the wire loop; although Dr. Delavan approved highly the method of Dr. Harrison Allen, contained in an article in the *American Journal of the Medical Sciences* for January, 1880. With regard to Dr. Shurley's case, there seemed to be more than a suspicion that it was due to syphilis, and similar cases were reported in which only a negative history could be obtained.

At the Afternoon Session, Dr. Beverley Robinson, of New York, read a communication on *Impaired Cardiac Power as an Efficient Cause of Congestive Affections of the Throat*, in which a central cause for some chronic throat disorders was pointed out, and the importance of general treatment made manifest.

A paper on

PHARYNGEAL IRRITATION,

by Harrison Allen, M.D., of Philadelphia, was read, in the author's absence, by the Secretary.

The object of this paper was to invite attention to the relations existing between the various movements of the pharynx and the irritable conditions of the passage as recognized in practice. The subject was divided into three portions—the irritation of the naso-pharynx, of the oro-pharynx, and of the laryngo-pharynx. The causes of disturbed action of the *naso-pharynx* reside, it was thought, in the forced elevation of the vellum, due either to over-action of the levator palati muscles, or paresis of the depressors of the velum. The action could with ease be studied through the nose in persons having capacious chambers. The mechanism is further modified by the presence of the naso-pharyngeal tonsil. The unnatural condition of the parts in the *oro-pharynx* are numerous. One of the most common is want of tonicity in the muscles on one side of the passage. This results in asymmetry, an effect chiefly seen in the palato-pharyngeal folds and on the sides of the uvula. The weakened or paretic palato-pharyngeus muscle assumes a nearly vertical position, and in the act of gagging moves scarcely at all toward the median line. When all the structures on one side of the oro-pharynx are atonic, the tonsils sag inward; and if large infra-tonsilar glands are present, persistent irritation of the parts ensue. The paresis of the sequelæ of diphtheria is, in the author's judgment, always bilateral, while that of syphilitic angina is always unilateral. The irritable states of the *laryngo-pharynx* may be excited by comparatively trifling causes—a result most likely due to the high degree of sensibility normally present here. The inferior constrictor muscle might well be called the guardian of the laryngeal orifice, and on the slightest provocation it enters into active constriction of the passage, and aids in the act by which the rima laryngis is closed. If the smallest extraneous particle lie in the region of the laryngo-pharynx —in the pyriform sinus or adjacent parts—the irritation is extreme. Similar troubles may arise from an engorged follicle or closed gland.

In conclusion, it was thought that a careful study of all the causes entering into the disturbance of mechanism was required before pharyngeal irritation could be with certainty removed.

The President exhibited a case of *Aphonia Spastica* in a middle-aged man, otherwise apparently in good health. The affection came on rather suddenly nearly a year before without assigned cause; he appeared to be getting better. Treatment by galvanization was recommended, with vocal gymnastics, and general nerve tonics.

Dr. Wm. H. Daly, of Pittsburg, read an interesting paper on *Catarrh Involving the Antrum of Highmore, and its Treatment*, in which the details of two cases were given. The treatment was the same as for abscess, perforation through the socket of the second molar tooth, extracted for the purpose. The teeth were healthy; the disease apparently began in the nasal chamber as a catarrh. The odor of the retained secretion was very offensive.

Dr. Carl Seiler opened the discussion

ON THE NATURE AND FORMS OF LARYNGEAL ULCER, SPECIALLY THE SO-CALLED CATARRHAL ULCER.

He said that he recognized the importance of the subject of deciding whether true ulceration of the mucous membrane was always due to a specific cause, or whether there was a kind of shallow ulceration met with in ordinary catarrhal inflammation.

He said that abrasions of the mucous membrane, which were nothing but localized loss of epithelium, occurred frequently in those portions of the larynx which were most exposed to friction, such as the inter-arytenoid space, the edge of the epiglottis, etc. These abrasions were by many regarded as ulcerations, but they were never covered with pus.

Occasionally, shallow round or lenticular ulcerations, covered with a white pus-like secretion and penetrating through the epithelial layer and the basement membrane into the sub-mucous tissue, were seen in catarrhal inflammations, in which no specific cause existed. These were the so-called catarrhal ulcers.

Thus, in the syphilitic laryngitis, two kinds of ulcers were observed—the shallow, and the deep and destructive kind. The peculiarity of the syphilitic sores was that they are always bilateral, and more or less symmetrical on either side, that their edges are raised and surrounded by an areola of deep inflammation, and that they are covered with a thick creamy pus. The deep syphilitic ulcers were always due to a breaking down of gummata in the mucous membrane, and they appear very rapidly—destroying a great deal of tissue in a short time.

The phthisical sore, on the other hand, was usually unilateral, non-symmetrical, appearing often on that side of the larynx corresponding with the side on which the greatest amount of lung implication is noticed. They are usually round, and tend to run into each other; their edges are not raised above the level of the mucous membrane, which is pale, even close up to the ulcer. They are covered with a grayish pus, and are rather slow in their development and progress. They are caused by the breaking down of cheesy deposits in the mucous membrane. The ulcerations of lupus closely resemble those of syphilis, so that it is often difficult to make a differential diagnosis.

Carcinoma, epithelioma, and leprosy give rise to ulceration of the mucous membrane of the larynx, and considerable destruction of tissue; having, however, no distinctive features, being easily recognized by other symptoms and appearances characteristic of the disease giving rise to them.

The discussion was continued by nearly all present; no agreement was obtained upon the pathology of catarrhal ulcer.

Wednesday, June 14.—The Secretary, for Dr. Clinton Wagner, of New York, read a descriptive paper on a case of *Ossification of the Right Arytenoid Cartilage. Separation and Expulsion following Thyrotomy for the Removal of a Papilloma*, and the specimen was passed around for examination. Dr. Seiler reported two cases of a similar character, and attributed the condition to a chronic sore throat in a syphilitic subject.

S. W. Langmaid, of Boston, made a few introductory remarks upon *The Singing Voice, its Physiology, Pathology, and Treatment*, which led to general discus-

sion upon the influence exerted by disorders of the upper air-passages upon the singing voice, and the propriety of interference.

J. O. ROE, M.D., of Rochester, opened discussion on *The Utility or Non-utility of Local Applications in Chronic Catarrhal Laryngitis*, in which he strongly recommended local applications by means of medicated sprays, or with the cotton-holder, using astringents and stimulants.

DR. DEBLOIS exhibited a pair of laryngeal forceps of original design, and also an instrument for applying the wire snare in operations upon the nose.

DR. SHURLEY exhibited his galvano-caustic knife for operations in the nasal chambers; and Dr. Rumbold explained his spray-douche, and showed its action.

The Society went into an election for officers, and the nominees already named were elected. DR. LEFFERTS, the President-elect, was inducted into office, and made a brief acknowledgment of the honor conferred.

THE AMERICAN MEDICAL ASSOCIATION.

Thirty-third Annual Meeting, held at St. Paul, June 6, 7, 8, and 9, 1882.

(Specially reported for THE MEDICAL NEWS.)

SECTION ON SURGERY AND ANATOMY.

TUESDAY, JUNE 6.—The Section met at 3 P. M. Owing to the death of the Chairman-elect, Dr. J. C. Hayes, of Iowa, the Secretary, DR. WM. BYRD, of Illinois, was elected Chairman, and DR. HUGH MCCALL, of Michigan, Secretary.

DR. CARL SEILER, of Philadelphia, made some

REMARKS ON THE USES OF ELECTRICITY IN SURGERY,

in which he gave a description of a galvano-cautery battery, devised by himself, and of an electric motor originally used for running sewing machines, but admirably adapted for a surgical or dental engine. The galvano-cautery, he said, had not been used more often because the batteries in the market are either too large and cumbersome or else so complicated as to easily get out of order, and also because the current could not be graduated, so that any desired heat of the knife could be obtained during the operation and without interrupting the current. He had found that the dull red heat of the knife was very painful both to the skin and mucous membrane, but an incision made was not followed by bleeding; a bright cherry heat was painful to the skin, but not to the mucous membrane, and an incision with the knife at this temperature was also bloodless; the knife at a white heat was painless both to mucous membrane and skin, but that it cut like cold steel and the hemorrhage was very copious. He therefore always used the cherry heat for operations in the nasal cavity. The gradation of the current and heat was obtained by having the zinc-plates of the battery suspended above the cups containing the carbons and fluid in such a manner that they can be immersed to any desired depth by means of a foot-treadle, and thus a greater or less amount of current was generated. In order to overcome polarization of the battery, which prevents continuous action, the battery has two cups and the zinc-plates are hung on a bar balanced in the centre above the cells. Thus if one series of plates is immersed in the fluid, the other is exposed to the air, which removes the hydrogen globules adhering to the zinc surface. By a rocking motion of the treadle the plates are immersed alternately, thus always exposing a fresh surface to the acid and keeping up the current for any length of time.

The electric motor he had used for some time past, and had found it far superior to the dental engine in operations for the removal of exostoses from the septum, or other bony obstructions in the nose, and also for freshening the surface of indolent ulcerations with the corundum cone. The motor is the smallest ever made, weighing only one-half pound, but nevertheless it had more power than the dental engine, and its revolutions can be regulated from 100 to 60,000 per minute, by the battery belonging to it. Another very great advantage of the instrument is the freedom from motion of the hand holding the hand-piece, which, when the dental engine is used, is very perceptible, being communicated from the foot working the treadle of the fly-wheel to the whole body, and materially interferes with the delicacy of touch necessary in many of the operations about the mouth and nares, for which the rapidly revolving drill or burr is so admirably adapted. The motor is suspended from the ceiling by a movable arm, over which cords run carrying the counter-weights. In this way the motor can be placed in any position desirable, and the hand of the operator is relieved from all weight except that of the hand-piece holding the drill. There is but very little noise connected with the revolutions of the motor, and he had not found that patients complained of the noise. Another advantage was that the cost of the motor, and the battery belonging to it, was considerably less than that of a good dental engine.

DR. DAVID PRINCE, of Illinois, said that he had used the thermo-cautery recently in many cases where he had formerly used the galvano-cautery, and was well pleased with it.

GASTROTOMY FOR THE RELIEF OF INTUSSUSCEPTION.

DR. WM. HILL, of Bloomington, Ill., presented a report of a case of ileo-cæcal invagination, operated on August 23, 1855, with recovery.

DR. PECK, of Iowa, referred to a case of intestinal obstruction treated by large injections, without relief; finally, upon abdominal section, the appendix vermiformis was found adherent to the vertebral column, and a loop of the bowel constricted by it. He tied the appendix with a double ligature, cleaned it thoroughly, and, relieving the obstruction, closed the abdominal wound. The patient is still living and improving.

DR. HALLEY, of Kansas City, referred to a case in which he proposed abdominal section, but was refused. The patient died, and at the autopsy the obstruction was found to be caused by a bony growth. He also referred to a case in which he had operated, where the obstruction was caused by a complete valvulus of the splenic section of the colon. The patient died. Still he believed the operation a justifiable one, and, in order to obtain good results, that it should be performed early.

DR. LEE, of Chicago, referred to the proper time to operate in these cases, and stated that too much reliance could not be placed upon the temperature and condition of the pulse, and that an operation to be successful should be done early.

DR. PRINCE, of Illinois, referred to the use of Wales's bougie, which could be introduced quite a distance, and the use of warm-water injections through it. If this did not succeed, then he advised an operation, but did not favor the operation in the early history of these cases, unless the symptoms were urgent.

DR. PARKS, of Illinois, spoke of three reasons why the operation was not more frequently resorted to.

1. Fear of meddling with the peritoneum.
2. Difficulty of diagnosis of the position of the obstruction.
3. The difficulty of determining the proper time to operate.

With our present means there should be no hesitation about the first.

The second would always be a difficult matter to overcome.

As to the third, the serious time was previous to the sixth day. In obstruction caused by feculent accumulation the best treatment in his experience was large doses of opium.

Dr. Hill advocated the early operation.

The Chairman thought that injections of water were of no value where the obstruction was not in the colon and strongly advocated the early operation.

Dr. C. C. F. Gay, of Buffalo, read a paper on

ANCHYLOSIS OF THE HIP IN THE STRAIGHT POSITION TREATED BY FRACTURE.

The case promised well, but left the hospital and final result was not known.

Dr. Hill reported a case where fracture occurred in an attempt to break up fibrous anchylosis followed by caries, necessitating resection, and recommended non-interference where the deformity was not too great.

Dr. D. Prince recommended the breaking up of anchylosis where the tendons are not much contracted, and thought the breaking up of adhesions of the hip-joint following diseases of that joint very dangerous, and that they should be left alone or only the tendons cut to allow if possible the restoration of some motion.

Dr. Poore, of New York, thought it dangerous to fracture in cases of anchylosis, but recommended osteotomy.

Dr. Owen, of Illinois, agreed with Dr. Poore that the day for fracture of the femur in anchylosis is past, and that there is neither shock nor danger from osteotomy as compared to the old operation of fracture.

Dr. Andrews, of Chicago, reported a case of death from shock, where osteotomy of the neck of the femur had been performed.

Dr. McCann, of Pennsylvania, advocated the division of resisting tendons before operating.

Dr. Lee, of Chicago, spoke of the difficulty in getting a joint, and stated, if the object were to correct the deformity, that osteotomy would be preferable on account of the absence of shock, while if a joint was desired, fracture would be more likely to succeed.

Dr. Ransohoff, of Ohio, said that in thirty cases seen by him only one case of death occurred, and that not from shock, but from gangrene and caries.

Dr. Halley, of Kansas City, had performed osteotomy twice with good joint in one case and no shock whatever.

Dr. Gay, in closing the discussion, referred to the danger of breaking the saw in the operation of osteotomy.

A paper by Dr. J. H. Warren, of Boston, entitled

A NEW ANATOMICAL TRUSS IN THE TREATMENT OF RUPTURE,

was next read. It contained an account of the treatment for the radical cure of hernia, by injection into the hernial rings after the method used by Heaton, and the application of a truss designed by the author to be worn afterwards till adhesions became sufficiently strong to prevent the recurrence of hernia.

Dr. Andrews, of Chicago, said that Dr. Pancoast was the first to use subcutaneous injection for the cure of hernia. That there is little or no risk in Heaton's operation for inguinal hernia, and that a certain proportion will be cured, but that in femoral hernia it was dangerous.

Dr. Phillips, of Ohio, used a double canula, the inner one finished with a dome point, and he used Dr. Heaton's formula and believed the operation to be a good one.

Wednesday, June 7.

A sub-committee, consisting of Drs. B. A. Watson, of New Jersey, Peak, of Iowa, and Carpenter, of New York, was appointed, to which all papers read in the Section were referred.

A description of a

SPLINT FOR TREATMENT OF FRACTURE OF THE ELBOW,

by Dr. J. F. Stewart, of Illinois, was read by the Chairman.

Dr. George W. Nesbitt, of Sycamore, Illinois, read a paper on

UNUNITED FRACTURE OF THE FEMUR TREATED BY EXERCISE.

He reported a case of ununited fracture treated by rubbing the ends of the bones together, drilling, etc.; then put on a plaster-of-Paris splint, and the patient put on his feet; union resulted. This case was first treated by rest in bed, with long splints.

Dr. Keller, of Hot Springs, Arkansas, said that this case showed the result of bad treatment in the first place, and thought that no fracture of the long bones should be treated but by adjustment and fixation with some fixed dressing fitted and moulded to the parts, and that movable splints should not be used.

Dr. J. W. Carpenter, of Kansas, referred to a case of ununited fracture of the femur which was referred to him. Plaster dressing was applied, and in a short time union was completed. He thought the reason why plaster-of-Paris splints were not more frequently applied, was because physicians did not understand how to apply them properly.

Dr. J. L. Atlee, of Pennsylvania, referred to the advantage of using flannel next the skin in fixed dressings.

Dr. Garcelon, of Maine, spoke of a case of non-union of ten or twelve weeks' standing. The patient ultimately brought suit for malpractice, and while working up the case improvised a leather splint, which he bound firmly to the limb and limped about. When the case came to trial union was found complete, thus showing that plaster alone was not necessary, but some kind of fixed dressing.

Dr. Forbes, of Ohio, opposed the application of plaster primarily, and thought that the swelling should be allowed to subside before applying any fixed dressing.

Dr. Flanner, of Michigan, had been accustomed to use the legs of flannel drawers in the application of the plaster bandage, and stated that some cases would not unite with any kind of dressing.

Dr. Keller, said he did not wait for swelling to subside, but puts on the permanent dressing at once, and in case of danger from swelling uses enough cotton batting to compensate for the swelling. In compound fractures he uses the Bavarian splint.

Dr. L. A. Sayre, of New York, spoke of the desirability of applying the fixed plaster splint at once, and detailed his method of applying the same, stating that he had never seen any evil resulting when properly applied. Woollen should be placed next the skin, as it absorbs the secretions, and is much more comfortable. Watch the case carefully, and if swelling occurs, cut your dressing. In compound fractures dress as in simple, only cut windows opposite the wounds.

Dr. Garcelon asked if swelling had occurred, for instance, if you could not see your patient for eighteen or twenty hours, would you apply your fixed dressing or wait for the swelling to subside?

Dr. Sayre, would wait till swelling had subsided and then apply the plaster, but should put it up in fixed dressing at once if he could see it early and thus prevent a great deal of swelling.

Dr. McLean, of Ann Arbor, asked does non-union occur in your practice where fixed dressings are used?

Dr. Sayre replied that no cases of non-union have

occurred in his practice, nor had he seen a case where the splint was properly applied. The more they go about the better it is for them.

DR. MCLEAN stated that from the tenor of the discussion outsiders might get the idea that non-union would not occur if proper dressings were employed, and thought that it would be a pity if such an impression went out from this Section, for non-union takes place sometimes with all the care that can be bestowed, and with any kind of dressing that can be applied, and referred to a case in which he was called as a witness, and he had been censured by some of his brethren for giving an opinion in court on the following hypothetical case: Suppose a fracture of the humerus treated by short board splints applied to the arm by tapes, the shoulder and elbow allowed to move freely, would that be good surgery, and asked Dr. Sayre's opinion on that case.

DR. SAYRE said he would consider it a case of maltreatment. He stated that a great many things might interfere with union, the constitution of the patient having a good deal to do with the result to be obtained, and that we cannot guarantee union in any case positively.

DR. FREEMAN, of Illinois stated that the contact of the bones, either end to end or side to side, seemed necessary to union.

THURSDAY, JUNE 8.

The first paper was entitled

CONTRIBUTIONS TO THE SURGERY OF THE LIVER,

by DR. JOSEPH RANSOHOFF, of Ohio, the first being a case of *cholelithectomy*, in which he had opened the gall-bladder and removed calculi. The walls of the gall-bladder were stitched to the abdominal wall, then opened, and the obstructing stones removed. The chief point on which he dwelt was the positive diagnosis of stone by a fine aspirating needle touching the stone before operation, and claimed that this was the first case in which that had been done, as far as he knew. The second part was a history of a case of hepatic abscess, where repeated aspiration having failed to cure, an opening was made through the abdominal wall with the thermo-cautery, the wall of the abscess stitched to the abdominal wall, and an opening, through one-half inch of liver tissue, made into the cavity of the abscess, without the loss of one drop of blood. The use of warm water, for six or eight hours a day, to cleanse the cavity, without any carbolic acid, was continued, and the inspection of the interior of the cavity, by the use of the laryngoscopic mirror, revealed large sloughs, which were removed by forceps. The patient finally made a good recovery.

DR. ANDREWS, of Chicago, read a paper on

THE PROPER POINTS FOR INCISION IN THE DRAINAGE OF SUPPURATING KNEE-JOINTS,

referring to eight points of incision.

EXCISION OF THE INTESTINAL CANAL WHERE COVERED WITH PERITONEUM.

This was the Address of the Chairman of the Section, DR. WM. A. BYRD, of Illinois, and was referred to the Section for discussion.

Dr. Byrd gave a short *résumé* of the history of excisions of the intestinal canal, and referred to the good results in operation, and the freedom from danger with proper care in diet, etc. The chief interest centred in the use of a flap of skin for the closure of an artificial anus, after the septum or spur between had been broken down. He also advocated the cutting away at the time of primary operation of a portion of the intestines obliquely, and so unite them as to prevent the formation of a spur between the two ends, and the more ready closure of the artificial anus afterwards. Dr. Byrd, in conclusion, presented the following propositions:

1. Any portion of the alimentary canal may be safely excised, and stricture, cancer, perforating ulcer, and gangrene demand that it should be done.

2. The method heretofore adopted of suturing the divided ends of the bowel is dangerous, because tympanites, by pressing upon the heart and lungs, interferes with the vital processes in a patient already worn down by disease and shock, and by distention causes traction upon the sutures in such degree as in many instances to cause their giving way, which is followed by fecal extravasation, peritonitis, and death.

3. These dangers are to a great extent obviated by making an artificial anus, permitting the escape of the gases as they form.

4. Artificial anus is easily cured by a plastic operation, devised by himself.

5. If that portion of the bowel which constitutes the eperon be cut away at the time of the first operation, no future operation will be found necessary, as the artificial anus will close spontaneously by cicatricial contraction.

6. The successful cases reported in the paper prove the propositions to be true.

DR. RANSOHOFF referred to the method of Dr. Byrd as the application of an old operation in other localities of the body to a new use, being the method of closing exstrophy of the bladder, and for repair of the lower wall of the urethra, converting skin into mucous membrane. In the second place, he thought it dangerous to remove so much of the blood-supply of the bowel as would be necessary by the excision of the oblique section of the bowel, on account of the great part of the mesentery which would be removed in the operation, increasing danger of death of the intestines.

DR. PREWITT, of Missouri, agreed with Dr. Ransohoff in the danger of the operation which was recommended by Dr. Byrd. He thought that after the surgeon has opened the bowel and given free exit to the feces, he has done enough, as any attempt to remove nature's adhesions may only result in harm to the patient.

DR. BYRD said that he was glad that the let-alone treatment was brought forward, but was also glad he had not followed it, as in eighteen cases of strangulated hernia he had only lost three.

Dr. Prewitt said that he did not advocate the let-alone treatment, only not to break up the adhesions which nature formed for the safety of the patient.

DR. GARCELON, of Maine, asked, in cases of strangulated hernia where the bowel is dead, whether he would take away all the dead part and dissect up the bowel and bring the parts together.

DR. BYRD said unless the position was good and the opening close together, he would dissect up the bowel and complete the operation as he had described.

DR. E. M. MOORE, of Rochester, said he thought it was not well to interfere with nature's efforts at repair, and he recommended leaving the adhesions alone—even in femoral hernia, where the position is not so favorable for an artificial anus after the stricture of the bowel has been removed. He wished to enter a protest against the position taken by the Chairman.

The Section then adjourned.

CORRESPONDENCE.

WATER IN THE STOMACH AND LUNGS IN DEATH FROM DROWNING.

To the Editor of THE MEDICAL NEWS.

SIR: I desire through your columns to correct an error, in connection with the report in last week's daily

papers, of an autopsy made by myself and Dr. Cadwallader, acting Coroner's physician, of the body of a woman supposed to have been drowned in the river Delaware.

The reporters of the case, in their desire to dress it up as effectively as possible, have put *their own* interpretation upon the results of this autopsy, whilst making it appear to the reader that they are expressing *my* views; and inasmuch as these inferences do not seem to me to be fully warranted from a single, isolated case, and especially where there was no absolute proof that the death was *caused* by drowning, I do not wish to be considered as endorsing the rather premature conclusions attributed to me by these well-meaning, but overzealous reporters.

Certainly, the leading authorities all teach that the presence of water in the lungs and stomach (especially the former) constitutes the most reliable evidence of death resulting from drowning, and the entire absence of water from both the lungs and stomach in the autopsy referred to was certainly a very noticeable feature, *provided* we were certain that the death was caused by drowning, which we were not, as the case was one of a multitude of similar ones, on which the Coroner's jury pronounces the stereotyped verdict of "found drowned." It is evidently a very important point for the legal physicians to decide—what are the positive, unequivocal signs of death by drowning? It may, in truth, become the *vital* point to establish in a capital case, as would appear to be the fact in the now pending "Malley Case." But in order to establish an important scientific truth we should not be content with merely one or two experiments, but these should be repeated under varied circumstances, until every doubt is removed.

I may be permitted to say, in this connection, that I am now engaged in investigating the post-mortem appearances in cases of death from drowning, as a legitimate object of inquiry connected with medical jurisprudence; but I had not the remotest idea that the results of the late autopsy, which was made in strict privacy, and which was only part of a series of observations of a similar character, would have fallen into the hands of the ubiquitous "reporter," and been made to assume a coloring not designed by myself.

Very respectfully yours,

JOHN J. REESE, M.D.

316 S. TWENTY-FIRST ST., June 26, 1882.

NEWS ITEMS.

BROOKLYN.

(*From our Special Correspondent.*)

LONG ISLAND COLLEGE HOSPITAL.—Some changes are about to be made in the faculty of this school. The Chair of Surgery has been divided between Profs. Jarvis S. Wight and J. D. Rushmore, giving the branch of didactic surgery to one and clinical surgery to the other. Dr. B. F. Westbrook has resigned the position of Lecturer on Anatomy, and Dr. Tetamore has been appointed Curator.

THE COUNTY BOARD OF PHARMACY.—At a recent meeting of the Medical Society of King's County, Drs. Audley Haslett and J. D. Rushmore were chosen the Medical Members of the County Board of Pharmacy. They are their own successors, and are elected to serve for a term of two years, from July 24.

THE ASSASSIN OF DR. SCHENCK.—Francis G. Thomas, the would-be assassin of Dr. Schenck, whose narrow escape from death was reported in the "NEWS" of June 17, attempted to commit suicide at the jail on the night of the 18th ultimo. When discovered he was nearly strangled. He is bent on taking his own life, and requires to be constantly watched. Dr. Schenck is recovering rapidly.

(*From our Special Correspondent.*)

ONTARIO MEDICAL COUNCIL.—The annual meeting of the Council of the College of Physicians and Surgeons of Ontario, was held in Toronto on the 13th, 14th, 15th, and 16th of June, for the transaction of general business.

Dr. Bray, of Chatham, was elected President for the ensuing year, and the following gentlemen as the Examining Board:

Anatomy (descriptive), Dr. Fulton, Toronto; Theory and Practice of Medicine and General Pathology, Dr. A. S. Oliver, Kingston; Midwifery (operative and other than operative), Dr. Burdett, Belleville; Physiology and Histology, Dr. Tyer, Chatham; Surgery (operative and other than operative) and Surgical Anatomy, Dr. Caniff, Toronto; Chemistry (theoretical and practical), with Toxicology, Dr. Barrett, Toronto; Materia Medica, Therapeutics, and Botany, Dr. W. W. Dickson, Pembroke; Medical Jurisprudence and Sanitary Science, Dr. Nicol, Brampton; and Homœopathic Examiner, Dr. G. E. Field.

EDINBURGH.

(*From our Special Correspondent.*)

DEATH OF PROFESSOR SPENCE.—By the death of Prof. Spence Edinburgh has lost her most successful surgeon. He was born in 1812, and was appointed to the Professorship of Surgery in 1864. Although not possessing the world-wide fame of some of his predecessors, he was, nevertheless, a surgeon who, if judged by the success of his operations, and not by the originality of his talents, occupied no inferior place to even Syme, Liston, or Bell. Lister, during his tenure of the Chair of Clinical Surgery in this University, convinced all his colleagues in the Infirmary and the Hospital of the truth of his antiseptic surgery, except Spence, who, to the last, could never be brought to believe in the use of antiseptics. He held, that all that was required in the treatment of wounds, and in the conducting of surgical operations, was thorough cleanliness, such as could be attained by a free use of simple water, coupled with careful attention to the general condition of the patient, and to the perfect ventilation of the ward. And it is rather remarkable, that holding and practising these views he was able to produce statistics of operations, both major and minor, which were as good, if not better, than those of Lister. And, indeed, Lister acknowledged this when, in seeking to prove the benefit of his method as compared with the old method, he declined to contrast his results with those of Spence, which he held to be perfectly exceptional. Spence has made many contributions to surgical literature, of which his *Lectures on Surgery* will best preserve his reputation and memory. In these he has embodied a very extensive and varied experience, and has described the necessary operations in a very clear and practical manner. He was an excellent anatomist, and his dissections of the arteries of some portions of the body, preserved in the museum of the University, bear surprising evidence of his skill.

The candidates announced for the vacancy created by Prof. Spence's decease are Dr. John Duncan, Dr. Joseph Bell, and Mr. Chiene, all of them surgeons in Edinburgh, and holding appointments in the Royal Infirmary.

VIENNA.

(From our Special Correspondent.)

Combustio: Billroth's Pathology.—Early in the week Prof. Billroth exhibited a case of severe burn, and discussed the pathology of the injury in a different manner from that obtaining among French surgeons.

The patient, twenty years old, had burned himself on the right arm, by contact with a mass of red-hot iron. The entire flexor surface of the forearm was of a red color, very painful, and covered with blisters, of which several ran together to form larger bullæ.

Prof. Billroth is accustomed to differentiate between three degrees of burning, in opposition to Dupuytren, who distinguishes six.

In the *first degree* (hyperæmia) the skin is of a bright red color, painful, and, in consequence of the exudation of serum into the skin tissue, somewhat swollen. Desquamation of the cuticle often occurs, and the capillary blood-vessels are always distended.

The *second degree* is characterized by the formation of blisters, some of which immediately follow the burning, others some hours later. These vesicles are caused by a rapid flow of fluid out of the distended capillaries, which lifts up the horny layer of the cutis. The blisters, which originally contained pure serum, or serum mixed with blood, in further course, can become purulent. A crust is constructed, under which new epidermis is formed.

Both degrees can be artificially produced by the application of vesicants.

By the *third degree* is designated that intensity of a burn in which the deeper situated soft parts are reached, and gangrene follows. This degree is always attended with the free production of pus, and the wound heals by the formation of granulations.

This division is made with relation only to the intensity of the burn. In regard to the extent of surface involved, it is worthy of note, although very little explained by physiological research, that it only requires two-thirds of the body surface to be burnt in order to secure certain death, with symptoms of dyspnœa and collapse.

Treatment must be directed entirely to the alleviation of pain, as the formation of skin cannot, in any way, be accelerated.

In the present case, after puncturing the larger vesicles, and empyting their contents, the forearm was enveloped in cotton.

Other methods consist in application of cold compresses, or in smearing the burnt surface with oil, in order to lessen pain. With collodion, which has been recently highly recommended, Prof. Billroth has obtained no favorable results. He succeeds very well, however, in burns of the third degree by compression of the burnt part with strips of sticking plaster, or by application of compresses, saturated with a one per cent. solution of argentum nitric.

The New York County Medical Societies and the New York Code.—The Chenango, Warren, Schoharie, Oswego, Montgomery, Westchester, Genesee, and Wyoming County Medical Societies are the latest to formally condemn the new Code.

The Public Health.—For the *week ending June 10*, there were 25 deaths from *small-pox* in New Orleans, the greatest number reported in any one week since the beginning of the present epidemic. There were 4 deaths from the same cause in Hudson County, N. J., and 2 each in Pittsburg and San Francisco. From *cerebro-spinal meningitis*, there were 7 deaths in Buffalo; from *scarlet fever*, 7 deaths in Buffalo, and 6 each in Hudson County, N. J., and St. Louis; and from *typhoid fever*, 4 deaths in Charleston.

For the *week ending June 17*, the following causes of death may be noted:

Small-pox.—There was a decrease in the mortality from this disease in Cincinnati and New Orleans. The deaths for the week were as follows: New York City, 6; Philadelphia, 4; Hudson Co., N. J., Pittsburg, and Detroit, each 1; Cincinnati, 37; Indianapolis, 2; Louisville, 3; and New Orleans, 15. There were two new cases reported in Buffalo; 5 in Pittsburg; and one each in Louisville and Nashville.

Cerebro-spinal Meningitis.—There were 9 deaths from this cause in New York City; 1 in Philadelphia; 3 in Hudson Co., N. J.; 5 in Buffalo; and 2 in Providence.

Diphtheria.—New York City reports 24 deaths from diphtheria; Philadelphia, 17; Brooklyn and Hudson Co., N. J., each 4; Boston, 7; Pittsburg, 6; Milwaukee, 5; and Cincinnati and St. Louis each 2 deaths.

Scarlet Fever.—There was a very marked falling off in the deaths from scarlet fever in New York City. The deaths for the week were as follows: New York City, 31; Philadelphia, 11: Brooklyn, 17; Hudson Co., N. J., 8; Boston, 3, and 13 new cases; Cincinnati, 9; St. Louis, 8; Detroit, 3; and Nashville, 2.

Measles.—From this disease there were 21 deaths in New York City; 1 in Philadelphia; 4 each in Brooklyn and Pittsburg; 3 each in Hudson Co. and St. Louis; 6 in Buffalo; and 2 each in Cincinnati and Milwaukee.

Whooping-cough.—New York City reports 13 deaths from this cause; Brooklyn, 6; Charleston, 3; and Pittsburg, 2. Elsewhere, no prevalence of the disease.

Consumption and Pneumonia.—There were 91 deaths from consumption in New York City; 38 in Philadelphia; 28 in Brooklyn; 29 in Boston; 18 in the District of Columbia; 11 in Cincinnati; 15 in New Orleans; 9 in St. Louis; 8 in Hudson Co.; 7 in Providence; and 6 in Buffalo. From pneumonia, there were 55 deaths in New York City; 35 in Philadelphia; 22 in Brooklyn; 10 in Hudson Co., N. J.; 14 in Boston; 8 each in Pittsburg and Cincinnati; 5 each in Providence and St. Louis; 4 in New Orleans; and 3 each in the District of Columbia and Pittsburg.

For the *week ending June 24th*, there were 4 deaths from *small-pox* in New York City and 4 in Philadelphia; 1 case reported in Boston; 29 deaths in Cincinnati; 5 new cases in Louisville; 1 death in Nashville. *Diphtheria* caused 37 deaths in New York City; 13 in Philadelphia; 14 in Boston and 39 new cases; and 2 in Cincinnati. From *scarlet fever* there were 39 deaths in New York City; 10 new cases and 1 death in Boston; and 8 deaths in Cincinnati. *Typhoid fever* caused 20 deaths in Philadelphia during the week. *Measles* and *whooping-cough* still prevail in New York City, but not to any great extent. The advent of warm weather has already had the effect of decreasing the number of deaths from acute lung affections; at the same time it has increased the mortality from diarrhœal diseases, but not to any great degree. Thus far this season there has not been any prolonged period of excessively hot weather in any portion of the country, and, consequently, infant mortality is not reported as excessive in any place, the death-rate from this cause being lower than it usually is at this season of the year. Excessive infant mortality will probably not occur before the second week in July, as the heated term has just commenced. It is sure to succeed the first week or two of very hot weather, and continue with fluctuations through the summer.

Health in Michigan.—Reports to the State Board of Health, for the week ending June 17, 1882, indicate that neuralgia, diarrhœa, and measles, have increased.

and that remittent fever and influenza have decreased, in area of prevalence.

Small-pox was reported present during the week ending June 17, and since, at 7 places, as follows: at Port Huron (one immigrant, convalescent), June 11; at Kalamazoo (two cases, convalescing), Detroit, Flint, and at Wayne County Pest House; at Grand Rapids (three during week ending June 17, three new cases June 21); at Battle Creek (one new case), June 22, 1882.

PROTECTION FROM INFECTION.—A meeting of representatives of the National, State, and Local Boards of Health was recently held in Port Huron, Michigan, at which the following resolutions were adopted:

Resolved, That we deem it important that a system of immigration inspection shall be immediately inaugurated, which shall apply to all trunk lines of railroad carrying immigrants, to prevent the introduction of smallpox into the United States and from one State into another.

Resolved, That the National Board of Health be requested to advise and co-operate with and through the State boards of health, and the several local authorities of health whenever it may be considered advisable to carry out a proper system of inspection and control of all persons travelling through the several States, with reference to the limitation of small-pox.

Resolved, That the National Board of Health be requested to erect or otherwise provide and furnish on the borders of States, as may be required, such temporary buildings as may be necessary, and provide for the care and maintenance of persons on emigrant trains suffering from small-pox, when committed to these hospitals.

Resolved, That, inasmuch as a considerable number of the immigrants coming into the United States or passing through them, necessarily travel through the Dominion of Canada, we do cordially invite the co-operation of the Canadian authorities in inaugurating a system of inspection of such immigrants in order to prevent, as far as possible, the spread of small-pox.

Resolved, That this conference commend the action of such transportation companies as have established a system of inspection and the issuing of protection cards and earnestly request all other steamship companies engaged in transportation to co-operate with local and other inspectors of emigrants in transit as a means of suppressing the spread of small-pox.

Resolved, That this conference is gratified to learn that many railway lines have already pledged co-operation in efforts of inspection, and we earnestly request all other railway trunk lines engaged in the transportation of immigrants to co-operate in inspection and the enforcement of regulations looking to the limitation of small-pox.

Resolved, That it is desirable that this system of immigrant inspection shall begin generally throughout the country by June 1, 1882.

THE NATIONAL BOARD OF HEALTH.—At the annual meeting of the National Board, held June 23d, the following officers were elected for the ensuing year:

President.—Dr. James L. Cabell, of Virginia.

Vice-President.—Dr. Stephen Smith, of New York.

Secretary.—Dr. Thomas J. Turner, Medical Director, U. S. N.

Executive Committee.—The above named officers, with Samuel F. Phillips, Esq., Solicitor-General; Dr. John S. Billings, Surgeon, U. S. A.; and Dr. P. H. Bailhache, U. S. M. H. S.

CENTRAL COMMITTEE OF THE ALUMNI OF THE UNIVERSITY OF PENNSYLVANIA.—The following gentlemen were elected on commencement day to represent the Medical Department in the Central Committee: John F. Meigs, M.D., John H. Packard, M.D., Caspar Wister, M.D., Samuel Ashhurst, M.D., I. Minis Hays, M.D., Albert H. Smith, M.D., William H. Van Buren, M.D., Traill Green, M.D., Claudius H. Masten, M.D., William H. Klapp, M.D. The committee met for organization last Wednesday.

NEW PARASITES.—We have before us a clipping from the editorial columns of a daily paper in which the recent investigations of Koch are humorously referred to. The editor then goes on to state that, "While Germany has thus given to the world a discovery of presumably vast importance, Wisconsin has not been idle. Dr. Buhl, a distinguished physician of that State, has just made a discovery as to the origin and proper treatment of broken legs which is, on the whole, rather more valuable than the discovery of Prof. Koch. It has long been noticed that broken legs prevail in thickly settled parts of the country much more generally than in thinly settled regions. It is also undeniable that wherever railroads penetrate broken legs soon become common. These facts are sufficient to enable us to assume that there is something in thickly settled regions that is favorable to the development of broken legs, and that this something—whatever it may be—is carried far and wide by railway trains. Dr. Buhl, who is an ardent believer in the germ theory of nearly all diseases, claims that he has discovered a vegetable parasite which infests the human trousers and causes broken legs. Within the past year he has examined with the microscope thirty-six cases of broken leg, and in every case has found this parasite in the accompanying trousers. In the course of the last six months he has placed garments cut after the manner of trousers and inoculated with the parasite in question upon the fore legs of eighteen cats, thirteen of whom were afterward found in a steel trap, set for the purpose in the doctor's back yard, each with a fore-leg broken. He also tried a similar experiment upon seven cows belonging to his wife, six of whom were afterward run over by railway trains—the White River and Sheboygan Railroad running directly through the cow pasture—and sustained compound fractures of more or less of their legs.

"Having thus fully established the fact that broken leg is produced by a parasite infesting the trousers, Dr. Buhl maintains, with much plausibility, that by inoculating human trousers with this parasite after it has been artificially bred in trousers supplied for the purpose to cattle, men will be fully protected against broken legs. So far as the non-scientific mind can perceive, the Doctor's plan is an admirable one. If we can by so simple a measure as the inoculation of trousers put an end to the wide-spread havoc yearly wrought by broken legs, humanity will owe to Dr. Buhl a debt which it can never repay, and the name of Buhl will be inscribed on all sorts of monuments by the side of the equally revered names of Koch and Jenner."

A GOVERNMENT ANIMAL VACCINE ESTABLISHMENT.—The British Local Government Board has just opened an establishment in London for animal vaccination with stables for the housing of the calves. Every precaution is taken that the calves shall continue in good health while they are resident in the institution. That they should be absolutely free from every blemish is most important, for apart from the question of the impropriety of using any but healthy animals, the fact remains that the least disturbance to the health of the calf materially interferes with the development of the vesicles. The calves are carefully selected, and those between four and six months old are found best to answer the purpose; if very young, they do not bear

well the change of food attendant upon their removal from the mother, and if too old, are difficult to manage on account of their size and strength. They are received at a fixed hour every Monday afternoon, and are carefully inspected by a veterinary inspector of Her Majesty's Privy Council before being admitted into the stables. Provided they pass this examination, they are then weighed and placed in their stall; here they remain under observation while awaiting inoculation. When ready to be vaccinated the calf is taken into the operating-room and placed upon the table, the top of which is arranged so that it turns upon hinges and is at first at right angles to the floor. When the calf enters the room it is again weighed, and then placed against the table in this position, and a strap is passed round its body and the top of the table; the latter is then placed in its ordinary position and retained there by bolts, the calf being by this movement raised upon it. The legs of the animal are then seized, one hind leg is strapped to an upright iron bar fixed to the table, the other in a horizontal direction, the forelegs and head are then secured, and the abdomen is thus thoroughly exposed. The latter is carefully shaved, and the lymph is inserted by means of a number of superficial incisions with a tenotomy knife charged with lymph. The lymph is either taken from tubes or directly from another calf; if from a calf, the vesicles are pinched up by curved sliding forceps, the crust wiped off, and one or two longitudinal incisions made into the vesicle to allow the lymph to escape. Lymph is in this way taken for the immediate vaccination of patients, or on points or in tubes, for future use, or for the vaccination of the next calf. The calf which has just been vaccinated is, on returning to the stable, provided with a cradle to prevent it licking the vesicles. This it wears until its own turn comes to supply the lymph, after which, of course, the cradle is no longer necessary.

The following arrangements have been made for the vaccination of patients visiting the institution. At half-past ten every Saturday a calf is vaccinated to supply lymph five days afterwards—that is, the following Thursday, when patients come at the same hour to be vaccinated; on Thursday lymph is also sent to the National Vaccine Establishment at Whitehall, and some is used for the direct vaccination of another calf, which, in its turn, is ready on the following Tuesday, at the same hour, to yield lymph for the purposes of further vaccination. The lymph at present in use is derived from a case of spontaneous cow-pox discovered near Bordeaux at the end of last year.

GEORGIA MEDICAL COLLEGE.—Drs. Lewis D. Ford and L. A. Dugas, two of the founders of the college, and for over fifty years members of its Faculty, have resigned. The Board of Trustees passed the following resolutions proposed by the Faculty.

Resolved, That, without debate and in response to the expressed wishes of Prof. Lewis D. Ford and of Prof. Louis A. Dugas, we accede to their relinquishment of the active duties of their Chairs, of the Practice of Medicine and of Surgery respectively, so long and so acceptably performed by them.

Resolved, That we unanimously recommend them for, and urge their acceptance of, Professorships *Emeriti* in their respective departments.

Resolved, That earnestly desiring to enjoy still the benefit of their wise and experienced counsel and of their influence in behalf of our venerable institution, we urgently request that they retain their membership in the Board of Trustees.

Resolved, That in their well-earned retirement and well-deserved rest, our revered colleagues will continue to hold, not only our warm affection and good wishes for their happiness and long continued welfare, but also that, for their part in the founding of this valuable institution of learning, and for their labors and watchful care of that institution in the promotion of the best interests of the medical profession, and of humanity which, with one other, they have continued for a period of half a century, they well deserve the respect and the gratitude of both the present and of the future generations.

SYRACUSE UNIVERSITY.—The commencement exercises of the College of Medicine of Syracuse University, New York, were held on Thursday evening, June 8. Eleven gentlemen were graduated, after having followed the graded course of that institution for three years of nearly nine months each. The address to the graduates was made by Dr. Wm. S. Ely, of Rochester, N. Y.

UNIVERSITY OF PENNSYLVANIA, MEDICAL DEPARTMENT.—At the Annual Commencement in June, the degree of M.D. was conferred on 5 candidates, making, with the 117 graduates in March, 122 for the collegiate year.

THE FRENCH ACADEMY.—For the vacancy in the Section of Anatomy and Physiology of the French Academy of Medicine, caused by the death of M. Moreau, the Section presented the list of candidates in the following order: MM. Mathias Duval, Ch. Richet, Laborde, and Farabeuf. Of the seventy-six Academicians present, M. Duval received the votes of fifty and was consequently elected.

DIED.—CARL HUETER, Professor of Surgery in Griefswald. Prof. Hueter was born in Marburg on November 27, 1838, in 1863 was one of Virchow's assistants, and for five years was an assistant to v. Langenbeck, when he was called as Professor and Clinical Teacher to Rostock, only in the next year to be summoned to Greifswald as successor to Bardeleben, a position which he held up to the time of his death. Hueter is best known as the author of a valuable treatise on "Diseases of the Joints," and the writer of the papers on Pyæmia and Septicæmia in Pitha-Billroth's "Handbook of General Surgery."

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT, U. S. ARMY, FROM JUNE 20 TO JUNE 26, 1882.

HOFF, J. V. R., *Captain and Assistant Surgeon.*—Having reported at these headquarters, is assigned to duty as Post Surgeon at Alcatraz Island, California.—*S. O. 107, Military Division of the Pacific and Department of California, June 17, 1882.*

DE LOFFRE, A. A., *Captain and Assistant Surgeon.*—Relieved from further duty at Fort Wallace, Kansas, and assigned to duty at Fort Sill, Indian Territory.—*S. O. 124, Department of the Missouri, June 21, 1882.*

BANISTER, J. M., *First Lieutenant and Assistant Surgeon.*—When relieved by Assistant Surgeon De Loffre, to proceed to camp of Ninth Cavalry, near Castonment, on the Uncompahgne River, Colorado, and report to the commanding officer for duty.—*S. O. 124, Department of the Missouri, c. s.*

NOTSON, Wm. M., *Major and Surgeon.*—Died at Columbus Barracks, Ohio, June 23, 1882.

THE MEDICAL NEWS *will be pleased to receive early intelligence of local events of general medical interest, or which it is desirable to bring to the notice of the profession.*

Local papers containing reports or news items should be marked.

ORIGINAL LECTURES.

A CLINICAL LECTURE ON PNEUMONIA.

Delivered to the Clinical Class in the Mercy Hospital of Chicago, May, 1882.

BY N. S. DAVIS, M.D., LL.D.,

PROFESSOR OF THE PRINCIPLES AND PRACTICE OF MEDICINE IN THE CHICAGO MEDICAL COLLEGE, AND SENIOR PHYSICIAN TO THE MERCY HOSPITAL.

(Reported for THE MEDICAL NEWS.)

(*Concluded from p. 3.*)

Symptoms and Diagnosis.—As practitioners of medicine, you are already familiar with the general symptoms of the disease under consideration, and I need not occupy your time in recounting them. I will, therefore, mention only those which, in connection with the physical signs, are diagnostic of the disease in the several stages of its progress. The commencement of the first stage is generally marked by a chill or chilliness accompanied by deep-seated pain and sense of oppression in one side of the chest; and its progress is indicated accurately by general fever with continuance of pain and oppression in some part of the chest coincident with the ready recognition, by auscultation, of the fine dry crepitant râle, and slight increased fremitus of voice; some cough with, at first, a very scanty viscid expectoration, but, which gradually increases, and after the first twelve or eighteen hours usually shows a slight intermixture of blood. During the transition from the first to the second stage, while exudation is going on actively, the fever heat increases, the expectoration becomes more mixed with blood, the dulness on percussion and fremitus of voice increase, and the fine crepitant râle gives place to one coarser and moist, called sub-mucous. When the second or exudative stage is fully developed, and the red hepatization is complete, the general fever is at its climax, the crepitant râle has entirely ceased, giving place to the ordinary mucous râle, and decided dulness on percussion over the inflamed parts. This condition, which constitutes the climax of the disease, is usually reached between the fourth and seventh days from the initial chill. During the next two or three days, in those cases which terminate by resolution, the general febrile symptoms rapidly decline, the temperature in some falling even below the standard of health; blood disappears from the expectoration; urinary secretion becomes more abundant; breathing slower and fuller; dulnes on percussion diminishes; and in some instances as the air cells first begin to reopen a return of the fine crepitant râle may again be heard at the end of the inspiratory act for one or two days. In such cases convalescence is usually well established in from seven to eleven days from the commencement of the attack. When the disease does not terminate by resolution, but has its second stage pass into a third, during which the exudative material is undergoing either purulent or caseous degeneration, the febrile symptoms, though modified in severity, are liable to continue one or two weeks longer, and the physical signs of the second stage to be equally protracted.

Treatment.—The indications to be fulfilled, or the special objects to be accomplished, in the treatment of pneumonia, vary with each successive stage in the progress of the inflammation.

In the first stage, characterized by increased excitability of texture and intense engorgement and distention of vessels, the plain indications are to allay the excitability and lessen the vascular fulness, and in the same ratio that we succeed in fulfilling these, will we lessen the amount of exudation and hepatization which is to constitute the second stage. When the latter has already supervened, however, then your leading objects must be to hasten the disintegration and promote the reabsorption of the exudative material, thereby inducing resolution before suppuration or caseous degeneration should supervene. If the latter processes do make a fair beginning, constituting the third stage, or that of gray hepatization, your main objects must be to lessen the degenerative processes and sustain the nutrition and strength of the patient. Such are the rational indications for treatment founded on the important pathological conditions present in each successive stage of the disease; but the particular means most efficient for accomplishing the several objects named, as well as the time and manner of their use, will be materially influenced by certain coincident conditions relating chiefly to the quality of the blood, and the general tonicity of the tissues. For while it is true that morbid excitability and accumulation of blood are constant elements or factors in the first stage of all acute inflammations, it must be remembered that the blood which thus accumulates in one case may differ much in its *quality*, and the relative proportion of its constituents, from that which accumulates in another case. So also the coexisting status of the vital affinity of the tissues, which regulates the molecular movements and general tonicity, may vary much in different cases. The composition and quality of the blood, and the vital affinity of the tissues, must be regarded, therefore, as the *variable* elements or factors in all stages of the inflammatory process. For instance, if a patient when attacked with pneumonia, has good plastic blood and an active vital affinity giving to all his tissues a good degree of tonicity, his case will present all the characteristic symptoms of an active sthenic grade of inflammation. On the other hand, if the patient when attacked had already been exposed to malarial influences until his blood was more or less impoverished of its red corpuscles, and nutritive constituents, with laxity of tissues; or if he had been living in the impure air of overcrowded dwellings, or in the midst of other conditions favoring typhoid developments, until the plasticity of his blood and the tonicity of his tissues were both impaired, his case would present all the characteristic features and tendencies of an asthenic inflammation. Again we have seen patients attacked with inflammation caused by the presence in the blood of some specific virus or contagium, the presence of which so modifies the symptoms and progress of the inflammation as to differ much from the ordinary sthenic or asthenic varieties. While it is true, therefore, that it is desirable to allay the irritation and lessen the vascular fulness in the first stage of all acute inflammations, whether sthenic, asthenic, or specific, yet the means for accomplishing these results most efficiently will differ much in the several varieties. Morbid susceptibility or irritation may be allayed by anodynes, anæsthetics, and sedatives; and vascular fulness may be diminished by lessening the quantity of blood in the vessels as by venesection, by increasing the contraction of the vessels themselves, through the influence of the vaso-motor nerves, and by lessening the action of the heart in forcing the blood into the vessels.

A careful examination of the actual clinical results obtained in the management of acute inflammatory affections during the last half century shows that in the first stage of the active sthenic grade of pneumonia one prompt and decisive venesection, followed by such cardiac sedatives as will lessen the force and frequency of the heart's action, is not only the most efficient mode of relieving the vascular fulness, and thereby limiting the amount of subsequent exudation, but it has been followed by the highest ratio of recoveries. In the same stage of those cases occurring in patients whose blood is already diminished in plasticity, and vessels more or less relaxed from malarious influences, from two to three decigrammes (gr. iij to v) of sulphate of quinia, given every two or three hours, alternately, with some mild cardiac sedative and alterant, will often as effectually check the vascular fulness as will the bleeding in the purely sthenic cases. In those cases, however, occurring in patients who are living in the midst of sanitary conditions strongly predisposing to attacks of typhoid or typhus fevers, the adjustment of remedies to meet the indications in the first stage is more difficult. In such patients direct depletion by bleeding is seldom borne without positive injury, and quinia frequently fails to produce the effect desired. When called to this class within the first twenty-four hours after the initial chill, I have usually ordered six powders, each containing sulphate of quinia 0.200 gramme (gr. iij); calomel, 0.066 gramme (gr. j); sanguinariæ, pulverized, 0.033 gramme (gr. ss); and glycyrrhiza, pulverized, 0.066 gramme (gr. i); one to be given every four hours, and four cubic centimetres (fl. ʒj) of the following mixture between:

℞. Liquor ammoniæ acetatis, 60 c.c., . . ʒij.
Tinct. opii et camph. 60 c.c., . . ʒij.
Tinct. aconiti rad. 4 c.c., . . ʒj.—M.

At the same time cover the whole affected side of the chest with a linseed-meal poultice; and if the skin is hot and dry, have all the surface not covered by the poultice frequently sponged with milk-warm water. As soon as the six powders have been taken, if the bowels have not moved spontaneously, they should be induced to move by an enema or a mild laxative. That the distinctions I have made in regard to the modifications or grades of pneumonia, and the variations which they require in the choice of remedies for fulfilling the indications presented in the first stage of the disease, are neither theoretical nor fanciful, but such as actually confront us at the bedside of our patients, I have had abundance of evidence in my own clinical experience.

From 1837 to 1847, I was practising in a hilly, rugged region, free from malaria, and supplied with pure air and good water, in the interior of New York, near the northern line of Pennsylvania, where the winters were cold, and during which attacks of pneumonia, pleurisy, bronchitis, and rheumatism were frequent, and uniformly of the sthenic type. In every case, when called during the first stage of the disease, I bled freely once and sometimes twice, and gave internally sedative doses of *tartar emetic*, alternately, with alterative and anodyne doses of calomel and Dover's powder.

The relief to the patient was always well marked, and sometimes so decisive as to render the amount of exudation in the second stage unimportant, and to enable the patients to be up and dressed, with all the indications of complete convalescence on the fourth and fifth days. In the spring of 1847, I moved to the city of New York, where, during a residence of little more than two years, I saw but few cases of pneumonia, and those among the poor surrounded by bad sanitary conditions.

In the autumn of 1849, I came to this city, then without sewers, and only a small part of it supplied with lake water. Yet the tide of immigration was such that every boarding-house was over-crowded, and we had an abundance of the idio-miasms added to the malaria naturally prevalent in the locality. Here, during the succeeding ten years, I had a rare opportunity for studying the modifying effects of malaria and the causes favoring typhoid fever on all the acute inflammations, both in their separate action and in all degrees of their commingling. I saw, during the latter part of winter and early spring of each year, many cases of pneumonia very promptly relieved by the free use of quinia in the first stage; while in other cases more strongly influenced by the causes of typhoid diseases, the quinia either produced but little apparent effect, or else added much to the dulness of hearing and stupidity of the mental faculties generally; and occasionally a case confronted me with all the characteristics of the sthenic type as strongly as I had seen at an earlier period in the interior of New York, and in which a prompt and full venesection had the same beneficial effects. In a few of the more severe attacks of pneumonia under strongly malarious influences, I have seen much benefit from one very early and free bleeding, followed by quinia in efficient doses. But I have never seen benefit from blood-letting in cases occurring in the midst of such sanitary conditions as decidedly favor the development of typhoid or typhus fevers. In the winter of 1850–'51, in a well-marked case of this variety, I opened a vein in the arm for the express purpose of ascertaining experimentally what the effect would be. Decided indications of syncope came before I had taken an ordinary *teacupful* of blood, and I was obliged to tie up the arm and administer carbonate of ammonia and camphor as restoratives. I have called your attention to the treatment of the first or congestive stage of pneumonia thus fully, because it is only in this stage that measures designed for directly lessening the vascular fulness, and consequently rendering the subsequent stages milder and shorter, can be used with benefit to the patient. When exudation has already taken place, and the second stage of the disease is fairly developed, further depletive and sedative measures are useless and generally injurious. In this stage, the continuance of poultices over the chest, and in some cases the addition of a blister, and the administration of alterant, anodyne, and expectorant mixtures, and mild nourishment, will constitute the treatment best calculated to promote resolution and prevent either purulent or caseous degeneration. The following is one of the best alterant, anodyne, and expectorant combinations that I have used:

℞. Ammoniæ muriat. 12.00 grammes, . ʒiij.
Ant. et pot. tart. 0.13 " . gr.ij.
Morph. sulph. 0.20 " . gr.iij.
Syrupi glycyrrhizæ, 130.00 c. c., . . ʒiv.—M.

Four cubic centimetres (fl.ʒj) may be given to an adult every three or four hours, mixed with a tablespoonful of water. If the urine is scanty, a mixture of two parts of liquor ammoniæ acetatis, two of spirits of nitrous ether, and one part of tincture of digitalis, may be given in doses suited to the age of the patient, half way between the doses of the other mixture. In most cases from two to three decigrammes (grs. iii to v) of quinia may be given with benefit, three times a day, until convalescence is established. There are some other items in the management of pneumonia to which I would like to allude, but the clinic hour is passed, and I must close for the present.

ORIGINAL ARTICLES.

THE TONSILS AND PHARYNGEAL IRRITATION.

BY HARRISON ALLEN, M.D.,
PROFESSOR OF PHYSIOLOGY IN THE UNIVERSITY OF PENNSYLVANIA.

THE tonsils have been for the most part studied only when they have obstructed the pharynx; for the relations between such obstructions and the acts of breathing, swallowing, and speech are so manifest, that those who run may read. These curious bodies, however, when not of sufficient size to create obstruction, have been ignored as possible causes of other phases of pharyngeal distress.

The following cases are presented as instances of pronounced trouble, arising from slight, but persistent, irritation from the tonsils and the allied bodies situated at the side of the pharynx.

CASE I.—Z., aged twenty-eight, contracted a cold eight years before, which had persisted up to the date of coming under treatment.

The symptoms at this time were: dropping of mucus, fulness in the back part of the throat, and pains in the chest. No symptoms were referred to the nose. Excessive quantities of mucus were constantly raised by gentle regurgitant acts from the laryngo-pharynx. It appeared to well up as from an inexhaustible receiver. Examination was made difficult, for when the mouth was kept open for a short time the fluid trickled into the larynx, producing a spasmodic cough which was very distressing.

The patient, a student of pharmacy, had the appearance of being overworked and underfed. The mucous membranes were pale, the edges of the folds and of the uvula were grayish and translucent. No infiltration anywhere existed. The lips were covered with whitish patches resembling the mucous patches of syphilis, but the existence of this taint was in no way confirmed by other signs, or by the history of the case. The patient did not use tobacco in any form.

This case was treated after approved methods; by spraying, local applications of astringents, by constitutional remedies, etc., for a month without benefit. At the end of this time a renewed careful examination revealed a small nodule lying on the left side of the pharynx below the tonsil. It was suspected as the source of irritation, and after three applications of the electro-cautery was destroyed. The symptoms were at once improved, and have now almost ceased.

CASE II.—Y., aged thirty-five, a bookkeeper, of spare habit, came under observation complaining of constant hacking and irritation of the throat, although no mucus was expelled by his efforts. The symptoms were of an aggravated, almost choreic, character. The throat was relaxed and flabby.

The uvula had been amputated by a practitioner in an abortive attempt to relieve the distressing condition. The case was under observation for a fortnight without relief, when the condition of the tonsils was suspected as a possible factor in the causation of the symptoms. These had not been noted in the previous casual examination of the oro-pharynx, for the reason that they were concealed within exceptionally deep tonsillar spaces. The relaxed palato-glossal and palato-pharyngeal folds had reduced these to inconspicuous chinks. Careful examination revealed on each side of the throat pea-like masses of indurated tonsil, pressing backward against the palato-pharyngeal folds. These bodies were destroyed by successive applications of the electro-cautery, and, after the subsidence of the inflammation caused by its use, the symptoms disappeared. Six months have elapsed since the treatment and the patient remains comfortable.

CASE III.—Miss O., aged twenty-four, suffered from irritation of the throat, referred to the right side. She complained of a sense of fulness, and her breath was exceedingly fetid. She reported for the last-named condition, which rendered her morbidly sensitive and almost excluded her from society. The disease had lasted three years, having been treated without permanent benefit by her family attendant, and by a prominent specialist in a neighboring city.

Careful examination revealed the palato-glossal fold stretched out as an operculum over the left tonsillar space and almost touching the palato-pharyngeal fold. When this opercular fold was drawn forward a number of tonsillar pellets were seen lying against the face of a flattened nodular tonsil, and the true nature of the case was at once evident. A diseased tonsil threw off the solid fetid pellets which are characteristic of this body, but owing to the peculiar disposition of the palato-glossal fold, they were retained in contact with the face of the gland instead of being ejected.

The opercular fold was removed with a pair of blunt curved scissors, the parts washed with a weak carbolic acid lotion, and the surface of the tonsil cauterized with the electro-cautery. The trouble at once disappeared and has not since returned.

CASE IV.—Miss X., aged thirty, referred to me by my friend Dr. Charles H. McCall, had been subject for years to neurasthenia, which had resisted the rest treatment and all other improved methods, until relief was at last obtained through the removal of the ovaries by Battey's operation. Among other symptoms accompanying the neurasthenia was a disposition to laryngeal catarrh, which would follow slight and apparently insufficient causes, such as a little fatigue, a slight change of temperature, or an attack of indigestion. There was also a sense of fulness referred to the region of the pomum Adami and the hyoid bone. She was excessively self-watchful and neurotic. Battey's operation had relieved the neurasthenia, but the pharyngeal symptoms persisted.

The throat was capacious, the palatal folds without infiltration, the tonsils were small, and did not press upon the palato-pharyngeal folds. The palato-glossal folds were not tense nor stretched over the tonsils. The parts were excessively irritable, and required careful training before the lower part of the pharynx could be exposed. The examination of this region revealed on the right side a red cock's-comb-like body, lying in the pharyngo-epiglottidean fold and projecting against the edge of a large epiglottis. The larynx was normal. The symptoms were entirely removed by applications to

the swelling just named. The electro-cautery was used upon small surfaces at a time, twice weekly for a month, great pains being taken to avoid inflammatory œdema of the glosso-epiglottidean space.

CASE V.—Mr. W., aged twenty-four, of fair complexion and with reddish hair, had contracted scarlet fever in childhood, and since that time had suffered from repeated attacks of tonsillitis. He contracted nasal catarrh in 1877, which was characterized by a semi-purulent discharge. This was shortly followed by symptoms of pharyngeal irritation, such as constant hacking, etc. There was a copious flow of perfectly normal mucus from the nasal passages, causing distressing efforts to dislodge it. Examination of the nose showed a slight deflection of the septum to the left, reddened membranes, and a thin, amber-colored crust overlying the under surface of the right middle turbinated bone. On the right side of the septum, at the premaxillary portion, was a small superficial ulcer which was occasionally the seat of moderate bleeding. Examination of the oro-pharynx showed intense hyperæmia, but no inflammatory thickening. The palato-pharyngeal folds were œdematous, and the velum elevated. The palato-glossal folds were relaxed and dusky, while the tonsillar spaces were concealed by two broad opercular bands. No view of the naso-pharynx was obtainable. The patient had been under medical care, without benefit, ever since the beginning of the pharyngeal distress, nearly four years before.

Under a treatment which consisted of spraying the pharynx, the use of gargles, and the administration of tonics, the nasal symptoms almost entirely ceased, and gave no annoyance. At subsequent visits, the naso-pharynx was successfully explored, but it exhibited no abnormal conditions whatever. Under the impression that a local cause of irritation was, however, somewhere present, the throat was again thoroughly explored. The tonsils were found to be mammillated and concealed by the palato-glossal and palato-pharyngeal folds. They were retroverted, so that their rugose, reddened surfaces were in contact with the swollen palato-pharyngeal folds, and it was accordingly suspected that here was the cause of the distress. Four free applications of the electro-cautery, at intervals of three days, completely removed the symptoms, and the hyperæmic appearance of the pharynx totally disappeared. The treatment was interrupted by an attack of acute rheumatism, but the patient reported again, after an absence of six weeks, so completely relieved that no further attention was necessary. It is of interest to note in this case that not only did the hacking and the flow of mucus cease, but the velum no longer remained elevated, nor did the middle turbinated bone throw out a plastic discharge. The tonsil, in a word, had not only kept the pharyngeal surfaces in a state of irritation, but had given rise to other symptoms which are usually traced to a different source.

The conclusion to be drawn from the above cases is simple enough. Pharyngeal irritation is often associated with a concealed tonsil or an infra-tonsillar gland, fretting the parts in their immediate neighborhood.

NOTE.—It is mentioned in the paper above that the pharyngeal irritation was associated with nasal disease due to obstructions. I have, in another place (*Amer. Journ. of Med. Sci.*, Jan. 1879), pointed out the causes frequently found in such cases, and the necessity of removing the projections from the nasal septum before recoveries can be established. It is now my custom, when the obstruction is in the premaxillary portion of the nose, in addition to filing or drilling away the osseous spurs or malformed sutures, to reset the triangular cartilage by detaching the inferior border from the triangular notch, to push the cartilage over to the larger side, and then drill or file away the projecting maxillary spur. This procedure I have now practised in eight cases, with very gratifying results.

OPIUM POISONING, FOLLOWED BY PNEUMONIA.

ARE STRIPPING, FLAGELLATION, VIOLENT EXERCISE, AND DOUCHING NECESSARY?

BY A. B. ISHAM, M.D.,
OF CINCINNATI, OHIO.

CASE I.—Mrs. B., æt. forty-four, was under treatment by Dr. S. C. Ayres, as a specialist, for catarrhal ophthalmia. The Doctor visited her the morning of the 3d of March, 1882, when he found her unconscious; she could not be aroused, the pupils were contracted to a pin's point and immobile, the respirations about two per minute, the pulse very rapid and feeble; the skin cold, clammy, and livid, and the attendants dragging her around, and slapping her vigorously with the palms of the hands. He learned that the previous evening she had suffered some neuralgic pains in the globe of the right eye, for the relief of which she had called in a homœopathic physician, who, within a period of ten minutes, administered two hypodermic injections of morphia, the amount of which it was stated he did not know, since he had carried the solution for six months, and had forgotten its strength. Dr. Ayres at once injected subcutaneously $\frac{1}{24}$ of a grain of sulphate of atropia, and declined further connection with the case, unless the medical attendant who had caused the trouble was discharged, and some one else called in with whom he could counsel. As the family could not at once decide to accede to his proposals, the Doctor took his departure, but yielded so far to entreaties as to promise to call in the evening and look at the patient. Accordingly at the evening visit the condition appeared yet of such gravity that his demands were yielded to, and, at his instance, I was called in to take charge of the case. On arrival, I found the patient clothed only in a thin wrapper and undergarment, which were both thoroughly saturated by the spilling of coffee, tea, brandy, milk, and water, in the attempts which had been made from time to time to pour these liquids down her throat. For twenty-four hours she had been incessantly moved about in a cold atmosphere, in rooms with windows open, and been slapped with the hands from head to foot. The atropia injection of Dr. Ayres was really about the only potent measure toward antagonizing the action of morphia which had been employed.

The pulse was 110 and weak, respirations 8 to the minute and sighing; the skin was cold, clammy, and livid; the pupils were contracted to a pin's head, yet they nevertheless exhibited the faintest sign of response to light. She was capable of being aroused, and could recognize persons. The symptoms of exhaustion seeming the most marked, it was directed that the clothing should be changed, and the subject placed in bed; stimulants were administered, and mustard plasters applied to the abdomen, legs, and feet

March 4, 7 A.M.—Patient fully conscious, respiration 23, pulse 110, temperature 102°. Coughing. Has bluish-black bruises all over the surface, everywhere; she is very sensitive to the touch, and complains greatly of soreness and exhaustion. 9 P.M., cough very distressing, temperature 102⅘°, pulse 122, dulness and crepitation at lower portion of right lung, front and back.

5th.—Rusty colored, thick, tenacious sputum; expectoration scanty and difficult; subcrepitant and fine mucous râles; temperature 104°, pulse 125. The pneumonia thus inaugurated pursued its course, and the patient was discharged convalescent March 23.

For the next case I am indebted to the courtesy of Dr. Wm. Carson, to whose service at the Cincinnati Hospital it pertained. The notes were supplied by Mr. Walter Christopher, under-graduate resident physician.

CASE II.—Victor Crook, French; æt. 40; barber; poorly developed and nourished; residence Urbana, O. Came to the hospital in the patrol wagon about 9 P.M. of March 30. Pulse rapid and full, respiration ceased, temperature about normal, face slightly cyanosed, pupils contracted to size of a pin-head, muscles completely relaxed, and unconscious. Administered at once $\frac{1}{16}$ grain of atropia hypodermically, and commenced artificial respiration. Within a half hour another $\frac{1}{16}$ grain of atropia was injected. In addition to carrying on artificial respiration by Silvester's method, flagellation of the chest with wet towels was employed to stimulate the act. About 10 o'clock P.M., the muscles of both upper and lower extremities became rigid, and there was also tonic contraction of the muscles of the back of the neck, and slight trismus, but no risus sardonicus. In about one hour these tonic contractions disappeared. During the greater part of the night no voluntary attempt at respiration was made, or else made at long intervals, and the act was almost entirely carried on artificially. At 4 A.M. of March 31, respiration could be excited by merely striking the chest, at which time the motion of raising the arms to produce inspiration was omitted, but expelling the air by compressing the chest was not discontinued. In a short time, however, the patient ceased again to make natural efforts at respiration, and the complete Silvester's method was again brought into use. At 6.30 A.M. the patient was able to carry on respiration unaided. About 7 A.M. he was taken to the ward, when the motion of transferring him from the stretcher to the bed again stopped respiration, which was, however, easily started again by the methods above mentioned. During most of the night the pulse was good, except a couple of intervals of about an hour each, when it became imperceptible at the wrist. In addition to several injections of $\frac{1}{60}$ of a grain of atropia, he received several hypodermic injections of brandy and whiskey. At 2 P.M. he could be roused by sharp questioning, but his answers were incoherent and unintelligible. He had again in the morning shown tetanoid symptoms, but no history of his having taken any strychnia could be obtained. The form of the poison used was morphia, but how much could not be ascertained. Toward evening, there was considerable elevation of temperature. He became fully awake, and could talk intelligently, but his movements were uncertain and jerky.

April 1, 5 P.M.—Resting easily. 10 P.M., very restless; high, weak pulse; temperature 103°.

2d, A.M.—Better; temperature 100°, P.M., temperature 102°; coughing.

3d, A.M.—Dr. Carson announced pneumonia. P.M., temperature 102.5°; pulse 124; respiration 55; crepitant râle in the right infra-scapular region; dulness over the right and left infra-scapular and scapular regions; rusty sputum. 7.10 P.M., died.

It has escaped mention in the above report that the patient was stripped to the waist in the accident ward for about nine hours, or during the time artificial respiration was practised, and besides his body was drenched with cold water by the flagellation with wet towels.

A considerable search through professional journalistic literature has not discovered other cases of pneumonia following opium poisoning. Dr. H. C. Wood, whom nothing is likely to have escaped, states in his work on Materia Medica, Therapeutics, and Toxicology, that opium poisoning usually has no sequelæ, and only gives a case of amaurosis taken from Schmidt's *Jahrbücher*. But it must not be overlooked that after opium ingestion, where death results, it supervenes rapidly, and that time enough is not given for pulmonary congestion to pass over into inflammation, or, if it does, it is likely not noticed, but considered part of the toxic action of the drug. Probably, too, this complication may not have been broached, from the fact that only a relatively small number of all the cases of opium poisoning which happen are published, and of these by far the greater proportion are those ending in recovery. In the reported cases the main point at issue is *treatment*, successful or unsuccessful. Consequently the attention has been directed solely to cause and antagonism to cause, and between these two nothing regarded as extraneous has been permitted to intervene.

What share a portion of the treatment employed had to do with the production of pneumonia in the two cases reported, may be settled to suit individual opinion. It is hardly possible that in both cases exposure and exhaustion were not without injurious influence. How many have been laid to the last long sleep by similar methods of procedure, the records do not show. They do show, however, that violent and excessive exercise, exposure, flagellation, and douching are unnecessary; that cases do as well, or better, where such expedients are not resorted to. And by thus showing that they are useless, they be-

come disclosed as cruel and barbarous, and therefore detrimental.

The above statements are supported by numerous published cases of opium poisoning scattered throughout home and foreign medical journals, which were successfully treated simply by atropia or belladonna, with rest and stimulants, including, of course, free emesis where the drug was taken *per orem*. Such means have proved ample for the recovery of apparently hopeless cases, in which there was no question as to the introduction of a fatal quantity of the poison, and in which the most alarming toxic effects were manifested. Dr. Oliver, of Philadelphia, in the *American Journal of the Medical Sciences*, 1876, has tabulated 256 cases of opium poisoning, of which one-half were subjected to the "belladonna treatment," and the other half to other methods. In the former the average percentage of recoveries was 96, and this is the series in which movement and exposure had the least place; while in the latter, where they always formed part and parcel of the other methods, the average percentage of recoveries only amounted to 74. Furthermore, the experiments of Drs. Corona and J. Hughes-Bennett upon animals leave no doubt of the power of atropia alone to prevent a deadly issue after the administration of a fatal dose of opium. While the main reliance, then, must rest upon the "belladonna treatment," there are some aids which have been, and yet may be, found advantageous. Such are the administration of caffeine and theine by hypodermic injection or *per orem*, the moderate employment of artificial respiration at intervals in special emergencies, and the use of a strong faradic current to cause pain, arouse the patient, and stimulate the flagging respiratory act. This latter has the merit of fulfilling these purposes to the greatest possible extent, and of leaving behind no marks, soreness, or exhaustion.

The treatment of opium poisoning may be thus summarized: Evacuation of the stomach by emesis or the stomach-pump, when the drug has been introduced by the mouth, atropia, caffeine, theine, stimulants, rest in a recumbent posture, sufficient clothing to retain the body heat, the considerate employment of artificial respiration where respiration is suspended, and electricity. All important indications are thereby met. By clearing out the stomach any unabsorbed portion of the poisonous agent is removed. Atropia, caffeine, and theine are respiratory excitants, and they favor the elimination of carbonic acid, with which the blood is surcharged in opium narcosis. Stimulants, rest, and warmth prevent the dissipation of the body strength and heat, and thus preserve to the tissues the greatest resistance-power to the poison. By artificial respiration, when the act is suspended, vital processes may be continued until force enough is gathered to make them self-sustaining. Finally, through electricity, impressions are made upon torpid nervous centres which call forth conscious and reflex respiratory and other efforts of value in overcoming the grave condition. Experience has fully demonstrated that this treatment combines all elements which are worthy to be relied on for rescue. In attempting to do more, is there not a culpable waste of more potent resources?

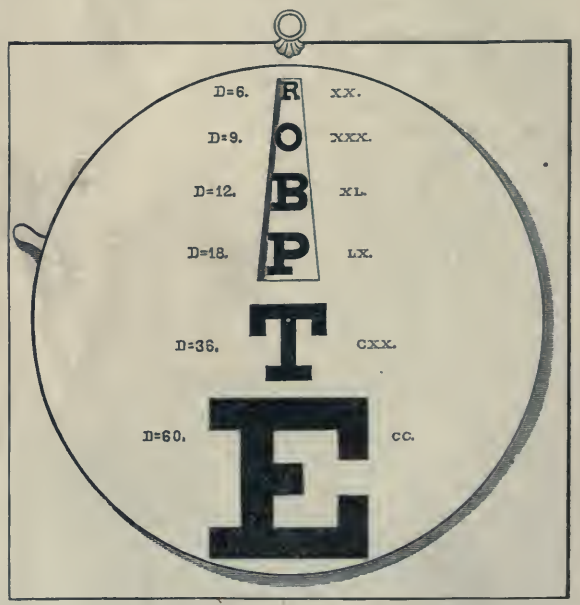
In closing, it seems fitting to give some of the conclusions of Dr. James Johnston, based upon a personal treatment of three hundred cases of opium poisoning, from the *Medical Times and Gazette*, of February 15, 1873. When the nervous centres are profoundly impressed, it is not only useless but mischievous to drag the individual about, as it only increases the exhaustion, which is one of the greatest dangers in cases of opium poisoning. The treatment for such cases is to place the patient in a horizontal position, inject atropia subcutaneously, if necessary assist it with artificial respiration, and, in cases of exhaustion, strengthen the circulation by applying warmth and counter-irritation to the limbs, and by the administration of stimulants, such as coffee, ammonia, brandy, etc. When the system is fairly under the influence of atropia, with respiration tranquil, however slow it may be, it is undesirable to interfere by artificial respiration, as it only embarrasses the breathing, and interferes with the tranquil sleep which usually follows the exhibition of atropia.

A TEST-TYPE DISK.

BY WILLIAM THOMSON, M.D.,
PROFESSOR OF OPHTHALMOLOGY IN THE JEFFERSON MEDICAL COLLEGE.

IN testing for the acuteness of vision of the employés of the Pennsylvania Railroad, it was deemed requisite to guard against any deception or bad faith, or at least to take precautions that the Snellen test-types should not be so accessible as to enable the men to examine them and learn them by heart. I was led, several months ago, to arrange the usual

FIG. 1.



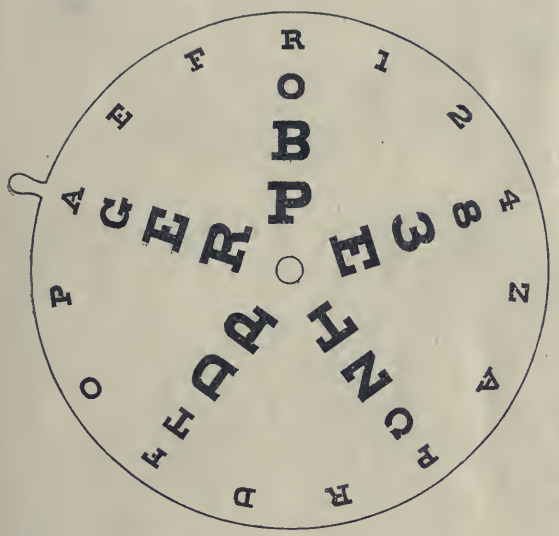
Upper disk.

letters in such a manner as to prevent any but one letter of a series from being visible at one time. This was done by using two disks of card-board,

about 12″ in diameter, superimposed, and fastened at their centres to a square of card-board, 14″ in each direction, which could be suspended upon the wall.

Upon the front disk (Fig. 1), near its lower border, was placed the letter D = 60. Over the centre was placed D = 36, and above this an opening was made by cutting out a V-shaped piece, to permit the letters on the second or lower disk to be seen. On this disk, above its centre, were placed, in concentric lines, all of the letters—D = 18, 12, 9, and 6, and in addition some figures of the same sizes, so arranged that, by the rotation of the second disk (Fig. 2), they could be brought into view at will through the opening in disk one.

FIG. 2.



Under disk.

This arrangement has been perfected, and will be furnished by Queen & Co., and I think it is worthy of description, since it will answer the purpose for which it was designed, and it also forms a compact, convenient, and useful form of the standard test-letters for office use, inasmuch as it prevents patients from learning all the letters of any given size with one eye before the other has been examined. The metric system has been selected, but the equivalent in English feet has been also placed opposite each series of dioptrics.

MEDICAL PROGRESS.

RESECTION OF THE PYLORUS.—LAUENSTEIN (*Centralb. f. Chir.*, No. 9, 1882) attempted the resection of the pylorus on the third of January, of this year, in a woman aged thirty-four years, with symptoms of cancer of the stomach, confirmed by the detection in the epigastric region of a tumor the size of the fist. In the operation an unexpected difficulty was met with; the stomach was closely adherent to the omentum, both at the greater curvature and by its posterior wall, necessitating the application of a very large number of ligatures, and the loss of a great deal of time, the operation lasting five hours. No unfavorable symptoms developed until five days after the operation, when peritonitis set in and rapidly proved fatal. The autopsy showed that the transverse colon was gangrenous at the point where its attachments to the stomach had been destroyed.

In a case reported by LEDDERHOSE (*Deutsche Zeit. f. Chir.*, xvi., 1882), the stomach was bound down to the pancreas, which was only recognized after having been cut; it was then attempted to free it by dissection, so causing considerable loss of blood and time, and requiring the use of the thermo-cautery. The operation lasted five hours, and the patient died during the course of the day from probable heart paralysis.

NYCOLAISEN (*Berlin. klin. Woch.*, 3, 1882) was equally unfortunate in the extirpation of the pylorus attempted on a woman presenting symptoms of cancer of the stomach with a perceptible tumor at the level of the eighth rib on the right side. Collapse occurred as the patient was recovering from the chloroform, and in spite of the administration of stimuli, she died in the course of the night.—*Gazette Méd. de Paris*, May 6, 1882.

PARESIS OF THE VOCAL CORDS.—DR. WHITFIELD WARD gives the following as a summary of his views on this subject:

1. That the arytenoideus muscle is the principal agent in the production of the affection styled paralysis of adduction.
2. That elliptical paralysis is caused by a paresis of the crico-arytenoidei laterales, through the inability of the latter bodies to revolve the arytenoid cartilages inward when approximated.
3. That the thyro-arytenoidei are the only relaxors of the vocal cords, and the type of paralysis produced by these muscular bodies is characterized by a perpetual tension of the vocal bands when adducted.
4. That the crico-thyroids are the only vocal tensors, and a paralysis of these latter muscles is manifested by the cords being permanently relaxed when approximated.—*Arch. of Laryngology*, April, 1882.

USE OF THE CARBOLIC SPRAY AS A PREVENTIVE AND CURATIVE OF SUPPURATIVE KERATO-IRITIS IN THE EXTRACTION OF CATARACT.—DR. GALEZOWSKI formulates the following propositions as expressing his results reached in a careful study of this subject:

1. The carbolic spray should form one of the indispensable conditions for ocular operations, and particularly for the extraction of cataract. The eye should be exposed to the spray during the entire operation, and after the operation is completed the eyelids should be widely opened and the spray directed immediately on the wound.
2. Each renewal of the dressing should be made under the spray.
3. Whenever, in the first three or four days, the least suppuration is detected at the border of the corneal wound, or an iritis with œdema of the eyelids, the spray should be used every half or quarter hour, according to the severity of the case.—*Gaz. Hebdom.*, June 2, 1882.

THE PRESENCE OF PTOMAINES IN THE INFERIOR ANIMALS.—M. SCHLAGDENHAUFFEN (*Journ. de Pharm. d'Alsace-Lorraine*, March, 1882) reviews the history of the important discovery of this class of organic poisons by the Italian chemists Moriggia and Battistini, in 1875, which were also observed at about the same time by Selmi, Casali, and Vella, and who called attention to their great importance in toxicology. More recently Brouardel and Boutmy, as also A. Gautier, have occupied themselves with the study of the formation of these bodies. According to the former, the ptomaines are the result of the putrid transformation of albuminous

bodies. They are most readily formed when the putrefaction takes place with exclusion of the air, and result from the union of certain hydrocarbons with the nitrogen proceeding from the tissues or from the animal liquids, while the oxygen of these materials and their carbon are dissipated in the form of carbonic acid gas. They may also be formed during life.

A. Gautier, whom Selmi was pleased to recognize as the first chemist to affirm the existence of ptomaines in putrefying matters, has expressed the opinion that they result from a division of the albuminoid matters. He has searched for them among the products of secretion of certain animals which are provided with special glands, and has confirmed their presence in the venom of reptiles.

Pursuing the thought of the physiological formation of these bodies, the question arose whether the salivary glands of the superior animals would not produce toxic substances analogous to the venom of serpents, and has indeed found in normal human saliva a very toxic substance, particularly in its action upon birds, in which it produces intense stupefaction. It consists principally of a venomous alkaloid, forming a soluble and uncrystallizable chloro-platinate and chloro-aurate, of the nature of the cadaveric alkaloids.

Based upon the interesting results of Gautier, the author has sought to disclose the presence of ptomaines in the inferior animals, selecting the comestible oyster and the common mussel as the subjects for experiment.

The animal, after having been detached from the shell, was deprived of the larger part of the tissue, in order to retain simply the central organ, the stomach and liver, upon which the experiments were made. The material was rubbed in a mortar with sand, which latter had been previously washed with acid and strongly ignited, and finally the organic material, after complete desiccation in a bath of salt water, introduced into an apparatus for continual displacement, and treated with hot ether. The ethereal liquid, evaporated to the consistence of an extract, contained a notable quantity of fatty matter mixed with chlorophyll, the presence of which was easily disclosed, either by the aid of the spectroscope or by means of concentrated hydrochloric acid. The ethereal extract was then extracted with water, without the addition of an acid.

The aqueous solution, evaporated to a convenient quantity, presented all the characters of the cadaveric alkaloids. It gave a yellowish-white precipitate with potassio-mercuric iodide and potassio-cadmic iodide. Iodine in potassium iodide, and the double iodide of bismuth and potassium, produced brown precipitates. Picric acid, phospho-molybdate of sodium, and tannin produced, likewise, abundant precipitates. Potassium ferricyanide, in contact with ferric chloride, gave rise to the formation of Prussian-blue. Its hypodermic injection produced in the frog a stupefying effect, but without causing death.

These characters agree with those of the ptomaines; and the author concludes from the above reactions that shell-fish contain bodies analogous to the vegetable alkaloids.

As to their origin, the author considers it difficult from the preliminary experiments to attribute their formation to a division of the albuminoid matters of the tissue, for nothing peremptorily demonstrates it; one would be able to refer them perhaps to a transformation of the alimentary bodies.

It would not be without interest to examine whether the production of ptomaines in animals is more abundant under certain physiological conditions than in others, or whether the toxic action of these bodies is more pronounced in summer than in winter. It is in order to elucidate this question that the author proposes to return again to the subject, after having investigated the reason, which is still the subject of controversy, why the consumption of oysters and mussels at certain seasons of the year is attended with danger.—*Amer. Journal of Pharm.*, May, 1882.

BLOODLESS OPERATIONS.—DR. JULIUS WOLFF, of Berlin, in a recent communication on the arrest of hemorrhage during and after surgical operations (Langenbeck's *Archiv*, Band xxvii., Heft 2), points out that most of the anticipated dangers of Esmarch's method do not exist. No instances have yet been recorded of such results from its application as plethora of internal organs, cerebral apoplexy, local inflammation, thrombosis, or gangrene. When persistent paralysis is met with as a result of constriction of a large nerve, it is usually found that the elastic band or ligature is composed of unsuitable material, or that it has been improperly applied. The danger, in cases of suppuration or sloughing, of putrid fluid, or unhealthy and softened tissue being driven into the circulatory system or the healthy structures, may be prevented by dispensing with the use of the elastic ligature, and by elevating the limb for a few minutes before applying the ligature. The most serious disadvantage attending Esmarch's method of constriction is the profuse parenchymatous bleeding, through temporary paralysis of the walls of the small vessels, which follows the removal of the constricting agent. Dr. Wolff describes the different attempts that have been made to prevent or guard against this result. In 1878, he proved that, during such operations on a limb as the removal of a sequestrum or the excision of a tumor, much blood would be saved by elevating this limb during the operation, and by its previous cooling through contact with moderately cooled air or water. He found that, by elevating the closed hand for a short time, he was able to lower its temperature by several degrees; and he stated that recent wounds, which, during elevation of the limb, remained almost quite dry, became at once flooded with blood after the limb had been laid in the horizontal position. After exposure of the upper extremity to air at a temperature of 42° Fahr., or water at 48° Fahr., such contraction of the small vessels results, it is stated, that, even when the arm is allowed to hang down, the thermometer grasped in the hand will not rise higher than 70° Fahr., and the hand and forearm will remain pale and cold. In operations on limbs, including major amputations, Esmarch, after tying all large and visible arteries, applies a firm and constricting dressing, and then removes the ligature. König, after the large vessels have been secured, removes the ligature, elevates the limb, and then looks for the bleeding vessels before finally covering the wound or stump. Dr. Wolff advocates the plan of covering the extremity of the stump by firmly bandaged antiseptic dressings, after removal of the constricting ligature, and before the application of the sutures, and of retaining these dressings, with the limb elevated, for a period of fifteen or twenty minutes, and until the stage of vaso-motor paralysis has ceased. The end of the stump is then again exposed, and, after deligation of any vessels that may still bleed, the wound is drained, closed by sutures, and then dressed. Three cases of amputation in the thigh are recorded in which this method was practised with success. The author recognizes the objection on the score of too much delay in the operation, and of the necessity of keeping the patient under the influence of the anæsthetic for at least a quarter of an hour after the removal of a limb. It is pointed out, however, that very often after the removal of the constricting band in amputation, much time is taken up in looking for and securing a number of small but freely bleeding vessels.—*London Med. Record*, May 15, 1882.

CLASSIFICATION OF THE MOTOR AFFECTIONS OF THE LARYNX.—DR. G. M. LEFFERTS adopts the following classification of motor affections of the larynx:

1. Motor paralyses of the larynx, the result of complete, usually acute, morbid implications of the nerve centres, or of the main nerve trunks, the lesion being either unilateral or bilateral, and the vocal cord or cords assuming the "cadaveric" position.

2. Motor paralyses of the larynx, the result of incomplete, usually slowly progressive, lesion of either the nerve centres, or, more commonly, of the nerve trunks in their course; certain nuclei of the former, or certain fibrils of the latter, alone being implicated, certain muscles alone are paralyzed; the abductor muscles of the glottis, possessing a peculiar proclivity in this respect, and practically being the only ones thus affected, the lesion may be unilateral or bilateral.

3. Motor paralyses of individual muscles of the larynx, the result of implication of certain peripheral nerve twigs, by local or intra-laryngeal lesions.

4. Motor affections of single or groups of laryngeal muscles, the result of simple myopathic change in said muscles of a degenerative character.

5. Motor paralyses, functional in their nature, the adductor muscles being the ones commonly affected, the abductors very rarely.—*Arch. of Laryngology*, April, 1882.

DEAFNESS COMING ON DURING AN ATTACK OF MUMPS.—Two cases, in which deafness suddenly supervened during the course of an attack of mumps, are recorded by DR. A. H. BUCK in the *Zeitschr. f. Ohrenheilk.*, xi. 26. In the first case the patient (a girl) was seized with very acute pain in the ear on the third day of the attack, and next day she was deaf. In the second case, the patient (a man) suffering from the same affection became deaf, but suffered no pain in the ear. In both cases both parotid regions were affected; nevertheless, in the first case the deafness was limited to one side. The author thinks that in both instances the deafness was due to some affection of the labyrinth.

Moos records (*Ibidem*, p. 51) the case of a boy of 13, who, on the fifth day of an attack of bilateral parotitis, became deaf. On the sixth and seventh days vomiting occurred; on rising from bed on the eighth day the patient's gait was staggering, but this symptom gradually subsided. There was no loss of consciousness. Tuning-forks c and c′ placed on the middle of the cranium, were heard in the right ear, but tuning-fork a′ was inaudible; all three forks were inaudible on the left side.

That he had here to do with an affection of the labyrinth, and not with a basilar meningitis, the author thinks most probable, as consciousness was throughout undisturbed. As regards the manner in which the affection is transmitted from the parotid gland to the organ of hearing, the hypothesis that this takes place directly, though by paths which are yet unknown to us, seems most plausible. But bearing in mind the fact that both testicles are not unfrequently inflamed during an attack of mumps, it seems to the author very probable that in many cases of parotitis certain materials enter the circulation, and, in passing through organs having a very complex circulatory apparatus (*e. g.*, the testicles or internal ear), especially when the return of blood is interfered with, are apt to be arrested, and to give rise to more or less disturbance.—*Glasgow Med. Journ.*, May, 1882.

THE SPLEEN IN SYPHILIS.—In order to be able to form a personal opinion about the liability of the spleen to be affected by the syphilitic dyscrasia, DR. BLOCH (*Hosp.-Tidende*, ix. 2 and 3, 1882) has examined the *post-mortem* records of the City Hospital of Copenhagen (Denmark) for fifteen years, viz., from 1866 till 1880, both included. He has collected 154 cases of *post-mortems* of children who had died with hereditary syphilis. In 96 of these the spleen was healthy. He gives the complete list, with details, of the fifty-eight cases in which the spleen was found in pathological conditions. These were hyperplasia, simple (14 cases) or combined with increased density of the tissue (31 cases), or with greater softness of the tissue than in the normal spleen (10 cases). Further, there was one case of infarctus, one of fibrinous exudation on the serous membrane, and one of thickening of the capsule and adhesion to the neighboring organs. Besides this he found in ten cases of hyperplasia fibrinous exudation on the surface of the spleen, four times thickening in different places of the capsule, and once adhesions to the contiguous parts. In eight cases there were found miliary tubercles, but always combined with tuberculosis of other internal organs.

Next Dr. Bloch examines to ascertain if the changes reported are referable to syphilis itself or whether they may as well be due to other diseases which occurred in individuals tainted with syphilis. He excludes three cases in which there were found tuberculous nodules in the spleen as part of a general tuberculosis. The great frequency with which hyperplasia is found warrants him to look upon it as a manifestation of the syphilitic dyscrasia, as described by Virchow and others.

On the other hand, the author does not think that the evidences of perisplenitis (fibrinous exudation and adhesion to neighboring organs) which were found in some cases are attributable to syphilis, since serous membranes nowhere else are found affected by syphilis.

The thickening of the capsule, he thinks with Virchow, is to be ascribed to present or past inflammation in the organ. He cannot determine from the report if the infarctus found in one case was a cicatrix as described by Virchow.

In no case of the 154 was there mentioned gummatous tumors, nor amyloid degeneration, and among 44 adults who had died in the course of syphilis during the same period, he found only three cases with amyloid degeneration, and none with gummatous tumors. These are indeed exceedingly rare in the spleen.

Dr. Bloch, in accord with Trapp, but in opposition to most other writers, thinks that the amyloid degeneration has nothing to do with syphilis, but when found in persons suffering from that disease is only due to long-continued suppuration.

Of the 44 adults suffering from syphilis, the spleen was found perfectly healthy in 14 cases; hyperplasia in 27 cases—11 times the soft variety, 16 times the hard. Together with the hyperplasia there was twice found thickening of the capsule in different places, and four times adhesions to the neighboring organs.

The hyperplasia then has been found in 61.4 per cent. of the cases of adults with acquired syphilis, while it was only found in 36.4 per cent. of the cases with hereditary syphilis. This seems to prove that it does not appear very early in the development of the disease.—*Arch. of Dermatology*, April, 1882.

IODOFORM IN DIABETES.—The last drug introduced into the treatment of diabetes mellitus is iodoform, which PROF. MOLESCHOTT, in a recent communication to the Academy of Medicine at Rome, states he has found to be very beneficial in five cases of that disease. The quantity of sugar excreted rapidly diminished in all the cases so treated. Small doses are sometimes productive of good results, but as much as forty and fifty centigrammes may be administered daily with impunity. The Professor employs cumarin—the odoriferous principle of the Tonquin bean—to overcome the un-

pleasant smell of iodoform. He prescribes—iodoform, 1.0; extract of lettuce, 1.0; cumarin, 0.1; to be made into twenty pills with powdered gum arabic, and to proceed from one pill twice to two pills four times in the twenty-four hours.—*Lancet*, June 3, 1882.

TREATMENT OF NASAL POLYPI.—In an elaborate article on nasal polypi in the *Deutsche Med. Wochen.* for June 3, 1882, DR. MAX SCHAEFFER condemns the use of polypi forceps as a means of removal of these tumors, as they cannot be completely eradicated, and what remains will cause their reproduction. He recommends the use of the galvano-cautery snare.

THE VALUE OF THE NUMBER OF VACCINAL CICATRICES IN THE PROGNOSIS OF SMALL-POX.—In deciding this question M. LANDRIEUX stated, in a note read before the Société Médicale des Hôpitaux, on May 26, that not only the number but the character of the scars must be taken into consideration, and the scars may be divided into genuine and spurious cicatrices. In 71 cases of variola with more than three genuine scars, three died, or 4 per cent., while in 98 cases with three or less genuine scars, twelve died, or 12.24 per cent.; of 143 cases with more than three superficial scars, 29 died, or 20 per cent.; of 133 cases with three or less superficial scars, 31 died, or 23 per cent. It is therefore seen that the number and character of the scars in a case of variola will serve as an accurate guide for forming a prognosis.—*Gaz. Hebdom.*, June 2, 1882.

EHRLICH'S METHOD OF DETECTING TUBERCULAR BACILLI IN THE SPUTA.—Among the many interesting specimens of micro-organisms shown to a large assemblage at the rooms of the Royal Medical and Chirurgical Society on Tuesday evening last, the 23d inst., there were two of especial interest, showing the bacilli of tubercle. They had been prepared by Dr. Ehrlich, assistant in the Medical Clinique, Berlin, according to a new method which promises by the excellence of its results to supersede that of Koch. One was a specimen of bovine tuberculosis, the giant-cells of which were the centre of interest; and the other was a preparation of phthisical sputum. It is chiefly on sputum that Dr. Ehrlich has made his observations, but his method is available also for sections. We take the following interesting practical details from the reports (*Deutsche Medicinische Wochenschrift*, May 6) of a communication made by him on May 1 to the Medical Association of Berlin (*Verein für innere Medicin*). He extracts, with a pair of needles, a small particle of the sputum, and presses it between two cover-glasses. He then separates the cover-glasses, and gets a thin layer of sputum on each. The cover-glasses are allowed to dry in the air, and, in order to fix the albumen, they are either kept for an hour at a temperature of 100° C. to 110° C., or they are passed two or three times through the flame of a Bunsen's burner. The coloring fluid is then prepared. Water is shaken up with an excess of anilin oil, and filtered through moistened filter-paper. To the clear fluid so obtained an alcoholic solution of methyl-violet or of fuchsin is added, drop by drop, until the fluid becomes opalescent. The cover-glasses, coated with the dried sputum, are then set swimming in this opalescent fluid, and in fifteen or thirty minutes they will have colored an intense blue or red, according as the violet or fuchsin had been used. Dr. Ehrlich now departs further from Koch's procedure; he does not color the substance in general with vesuvin, but he decolorizes it with strong acids, the bacilli retaining the blue color. One volume of officinal nitric acid is mixed with two parts of water, and the blue-stained preparations are put into this strong acid. In the course of a few seconds the color fades, a yellowish cloud passes across the preparation, and leaves it white. Everything in the preparation of sputum is now decolorized, except the bacilli, which are intensely blue. But the technical difficulties of seeing them are still considerable, and it is further desirable to color the ground substance yellow in the case of a methyl-violet preparation, and blue in the case of a fuchsin preparation. In the specimen of phthisical sputum prepared by Dr. Ehrlich as above, and exhibited on Tuesday last, the bacilli were very numerous, very uniform in size and form, and very distinct, the magnifying power being about 900 diameters and the illumination strong. Dr. Ehrlich has examined the sputa from twenty-six pronounced cases of phthisis, and he has found bacilli in them all, and most abundantly in acute cases. In most cases the bacilli are found in the very first specimen made, and in the very first field of the microscope. The entire process of drying and coloring may be done in less than an hour. The bacilli were not found in sputa other than phthisical. A friend sent him a specimen purporting to be phthisical sputum, in which Dr. Ehrlich could find no bacilli; and, on inquiry, it proved to have come from a case of empyema with perforation of the lung.—*Med. Times and Gaz.*, May 27, 1882.

PROPHYLAXIS OF OPHTHALMIA NEONATORUM.—CREDÉ (*Arch. f. Gynäkol.*, Bd. 18, H. 2.) has now treated four hundred cases in addition to two hundred previously reported, and with equal success. In consequence of the objection that the continued application of salicylic acid compresses was very probably the important part of the treatment of the earlier cases, the compresses were omitted in more than three hundred of the later ones, and the treatment thus rendered exceedingly simple. On division of the cord the infants were bathed, the lids washed off with a bit of clean rag and water only, then from a glass tube a single drop of a two per cent. solution of silver nitrate was dropped into each slightly opened eye. Nothing more was done. No one of the infants so treated became affected during the first seven days, even in slight degree, nor was there the least harm from the instillation. Children born at term showed practically no reaction, scarce reddening, never swelling. Only in a portion of the prematurely born, whose conjunctiva appears to be more easily irritated, there was after a short time an increased serous, followed by a little mucous, secretion, which, however, always disappeared in twenty-four to forty-eight hours. Credé insists that only direct treatment of the eyes themselves is a certain preventive of infection. Disinfectant cleansing of the maternal genitals before and during labor, though this also was carried out as much as possible, has been shown by experience to be insufficient of itself to prevent infection, and none of the other usual disinfectants has given the same certainty as the silver nitrate.

The mothers of the six hundred infants presented the most varying conditions; there were syphilitic, gonorrhœal, and catarrhal affections; some were clean, others very dirty, and the latter could not always be properly cleansed because entering the hospital during labor; there were easy labors, and very severe operative cases.

The above treatment, of course, prevents only such disease as is acquired during labor; this, it is generally admitted, appears at least on the fifth day. Any affection beginning later must be referred to another source. The latter cases occur but rarely, and their course is generally short and favorable, although serious cases are sometimes observed. For these a drop of the above solution should be applied at the beginning, repeated once daily, if necessary, and a small ice-bag be kept continuously on the lids.—*Boston Med. and Surg. Journ.*, June 1, 1882.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE, ... $5.00.
SINGLE COPIES, ... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made at the risk of the publishers, by forwarding in REGISTERED letters.

Address, HENRY C. LEA'S SON & CO.,
NOS. 706 & 708 SANSOM STREET,
PHILADELPHIA, PA.

SATURDAY, JULY 8, 1882.

GUITEAU—POST-MORTEM.

NOTWITHSTANDING the advances made in the means of observation, and in the interpretation, of changes discovered in the nervous centres in cases of mental disease, it still remains true that there is no necessary dependence of even extreme mental perversion on recognizable lesions. It is not safe to predict that, a mental disease being given, a certain series of morbid alterations must be found. On the other hand, the existence of very extensive disease of the cerebral structures is not incompatible with a perfectly normal state of the mental functions. It is becoming more and more evident, however, with the progress of knowledge, that the number of merely psychical derangements is lessening rapidly; indeed, there are now few psychiatrists, if any, who maintain that ancient theory of insanity which refers all cases to the domain of spiritual derangement, in which there are no discoverable lesions. The alterations in the psychic sphere are now generally referred to some change in the organic substratum.

Increasing experience, clinical observation, and experiment tend to show that minute alterations in the cortex suffice to produce extreme mental derangement, when extensive coarse lesions in the other parts of the brain have little influence on the operations of the mind. It is probable, indeed, that mere molecular changes in the gray matter of the mental sphere may much affect its functions. So much uncertainty attends the demonstration of these minute changes that there is a growing distrust regarding the genuineness of many observations. Post-mortem changes take place with such rapidity, the preparation of sections for the microscope so modifies the structure, and so high is the skill necessary to produce good results, that structural alterations, not demonstrable by coarser means, are looked upon with some uncertainty, if not with suspicion and distrust. Hyperplasia of the delicate neuroglia, granular clouding of the cells, amyloid bodies, etc., if alone discovered, and not accompanied by other distinctive evidences of pathological change, will hardly be considered to prove, in any doubtful case, the existence of insanity.

Applying these principles to the demonstration of Guiteau's morbid cerebral anatomy, it must appear, from the report of the autopsy, that those psychiatrists who expected to demonstrate the assassin's criminal irresponsibility, by the changes in his brain, will have a rather difficult task. If they expected to find deviations from the normal type of brain structure, the evidences of chronic meningitis, dilatation of the ventricles, atheromatous degeneration of the vessels, dilatation, fatty degeneration, amyloid change, etc., of the perivascular lymph spaces, wasting, or the *état criblée* of the gray matter, and the other numerous changes in the intra-cranial organs of the chronic insane, they are, certainly, disappointed. Some deviations from a typically normal brain are referred to in the report, but they have absolutely no signification from the point of view of mental derangement. Adhesions of the dura mater, and the thickening of the membrane, without any evidence of coexistent inflammation, cannot be said, indeed, to have any pathological significance.

It may be affirmed of Guiteau's brain, that it presented as little evidence of pathological change as the brain of any one of his age dying of some other than cerebral disease. What may be disclosed on microscopic investigation, which is yet to be made, remains to be seen. Here the opportunities are great for unconscious deception, and for differences of opinion. As the naked-eye appearances are so little suggestive of disease, the minuter changes must be well fortified by the skill and experience of the microscopists undertaking the investigation, to be accepted without reserve. There must be no preconceived opinions, no previous predictions, and no prejudices of any kind, on the part of the microscopic experts to give a bias to their conclusions. They should, indeed, enter on this investigation in the spirit in which the autopsy was conducted.

The examination, the record of which we print to-day, was made with the view to ascertain the pathological conditions and the anatomical peculiarities; the interpretation of these appearances as bearing on the question of insanity, formed no part of the duty of those making the autopsy. Let the

microscopical examination be conducted to the same end—to the demonstration of the actual condition, quite irrespective of the effect the conclusions may have on the opinions and judgments of those experts who have committed themselves in advance. We may advert to this subject when the report of the microscopical appearances is published.

CHINOLINE IN THE TREATMENT OF DIPHTHERIA.

As chinoline, recently brought forward as a substitute for quinia, has proved rather disappointing, it may interest our readers to learn that it has been employed in diphtheria with a considerable measure of success. In a series of papers now publishing in the *Berliner klinische Wochenschrift*, Dr. Seifert, of Würzburg, gives a number of cases in proof of its utility. A five per cent. solution is painted over the affected surface, and a two per cent. solution is used as a gargle. The results which follow are softening and detachment of the exudation, lessening of the glandular swellings, diminution of the fetor, and an improvement in the general state manifested by the decline in temperature and pulse. He also allows ice freely, but no other remedy appears to be used. If good results are obtained from treatment so little perturbating, it is really an important contribution to our resources.

This practice is not altogether novel. Quinia in solution sprayed freely over the throat, has been used in diphtheria with success, just as Seifert is using chinoline. It is not possible to estimate the quantity of chinoline swallowed, and hence the part in the result due to the systemic action is not separable from that due to the local. As Seifert only uses the remedy in applications to the locality affected, he probably considers the disease local at the outset, and hence most effectively treated by topical measures.

MALARIOUS WATERS.

THE Wheeling, West Virginia, daily papers of June 23, contain reports of a special meeting of the doctors of that city to confer with Dr. Charles Smart, U. S. A., and arrange for coöperation in an investigation into the propagation of malaria by water-supplies, undertaken under the authority of the National Board of Health. It appears that four cities have been selected for the purposes of this investigation—Yonkers, N. Y.; New Haven, Conn.; Paterson, N. J., and Wheeling, W. Va. The first has some local sources of malaria along the valley of the creek which furnishes its water power. The second, also, has some marshy spots which may complicate the inquiry; but Paterson, which suffers a good deal from malaria, appears free from local sources of exhalation. Wheeling, on the other hand, is reported by its professional men as being a non-malarious city. The experiment includes the weekly analysis of the water-supplies of these cities by Dr. Smart, while the medical men make note of their malarial cases, and report them weekly to the Board, that at the end of the year it may be observed whether there is any coincidence between the times of prevalence and certain results of the chemical investigations. Incidentally, during the summer, the ice supply will be examined; and where the physician in attendance on any malarial case unconnected with the city supply doubts the quality of the water used, and desires its analysis, arrangements will be made to have it examined. This is a good work, and we are pleased to learn that the busy practitioners of the cities in question have entered heartily into the matter, and will, without exception, report their cases in connection with the analytical work.

CURARE IN EPILEPSY.

THE important results obtained from the subcutaneous injection of curare or woorara, in epilepsy, may be a justification for a few lines on this topic.

In the first place, it should be noted that the specimens of this drug vary much in activity. Hence in beginning the use of a new supply, its strength should be ascertained by careful administration of minimum doses. Solutions are made by the aid of a little acetic, muriatic, or sulphuric acid, which may then be neutralized by sufficient ammonia added very cautiously. The solution should then be filtered. When kept for a time—for a few days, indeed—five minims of liquefied carbolic acid should be added to each ounce of solution, to prevent change.

In epilepsy this remedy was first used on a large scale by Voisin and Lionville, and by them was pushed to the utmost limits of safety. The most remarkable curative results have been obtained by Kunze. He injects a dose of about two and a half grains every five days, and this amount he says produces no distinctive physiological effects. Kunze reports three out of thirteen old epileptics cured by this treatment. If there is no improvement after four or five injections it is useless to continue it.

The reader, we hope, will not confound curare with *curarine*, the alkaloid discovered by Preyer. It is the crude drug to which reference is made above. Before administering the dose recommended by Kunze, the strength of the specimen should be ascertained.

CRUELTY TO HORSES.

FEW of us wish to be cruel to our faithful, dumb animals, yet how many are! Let any one try to pull a heavy burden, with his head in the air, and see how hard it is. We flex the neck involuntarily,

because we well know that that posture gives at once both the greatest pull and the greatest ease. As with man, so it is with the beast.

Yet our poor horses are reined up so tightly by the short bearing- or check-rein that their flexor muscles have no play at all. It is sheer torture to keep them so, hour after hour, merely to give a stylish appearance. To drive without any check-rein is impracticable. We have observed that a number of doctors have tried it, but, after a trial, they have abandoned it. The horse gets his head in the wet and the dirt, and soon presents a sorry appearance. But we plead for a very *loose* check-rein. Our horses are so faithful to us that gratitude as well as self-interest should be on the side of kindness. Again, now that the hot weather is upon us, we plead for at least one midday drink of water. The Fountain Societies have provided suitable drinking-troughs in many cities, and where they have not, there are usually facilities provided in front of many taverns. Any one who drives much appreciates very heartily the benevolence of such a provision for the wants of brutes.

While writing of horses, we venture to say a word as to that much vexed question, the horse-shoe. Any one who will take the trouble to examine, even casually, the anatomy of the horse's foot, will see that the frog is a wedge of elastic tissue fitted for concussion. Each time it pounds the earth, it spreads the hoof laterally by reason of its shape, for it is not only a wedge antero-posteriorly, but also vertically. It is fitted for concussions as perfectly as is the sole of the dog or the cat.

We know it is a moot point among even good horsemen as to whether in shoeing frog-pressure should be courted or avoided. Experience, we believe, will be in favor of frog-pressure, and both anatomy and common sense are on its side. The frog is precisely fitted, as we have said, for such pressure, and even our stony street pavements do but harden and develop the frog, just as the bare-footed boy has his foot-sole toughened. Xenophon tells us, in his school for horsemen, that colts brought up on dry, stony soils never need protection.

The ordinary shoe, with heel and toe cork, lifts the foot-sole from the ground, and prevents such frog-pressure. But, as a rule, such horses have more or less contracted heels, and have not a long, free stride. Their gait is "groggy." Take off such shoes, and put on the Goodenough or a similar shoe, and it is remarkable to see how their gait improves, and how the heel expands. In the winter time, owing to the ice, it is necessary to shoe them with corks say two or three times; all the rest of the year the Goodenough, applied cold, is by far the best shoe. We speak after considerable experience.

MEDICAL EDUCATION IN OHIO.

DR. JAMES E. REEVES, President of the West Virginia State Medical Society, in his address at the late annual meeting, which we gave on page 609 of our issue for June 3, has taken up a number of timely topics, and among others he alludes to the question of "cheap diplomas" in Ohio. With a Darwinian exactness, he gives facts to support his assertions. Precisely one month after application, a candidate just rejected by the District Board of Examiners at Wheeling, is said to have received his diploma from the Columbus Medical College, along with a class whose attainments in anatomy would be amusing were such ignorance not possible sources of tragical dangers to the community.

If the facts are *not* as stated, the Columbus Medical College, in justice to itself, should instantly and conclusively disprove such responsible and publicly made assertions. If they *are* so? Alas! we have no tribunal save that of public opinion at which such a college can be tried. But public opinion should make its sting felt.

We often hear vague assertions that some college has done suspicious things, but action can not be taken on mere suspicion. Here, however, is a specific case—names, dates, and all, with a responsible man back of it. Let us have the fullest investigation by the Association of Medical Colleges, of which, at the last report, this College was still a member, though a delinquent one.

We are glad to join with Dr. Reeves in commending the first-class colleges of Ohio, and are pleased to see that an Ohio journal (the *Cincinnati Lancet and Clinic*) has the courage to reprint the address. If such outrages exist, the colleges and medical journals of Ohio owe it to themselves, as well as to an imperilled community, not only to enter an emphatic protest against them, but to put a stop to them.

THE FEES OF THE MEDICAL ADVISERS OF PRESIDENT GARFIELD.

WHATEVER may be thought of the abstract injustice of the proposition made by Senator Vest, of Mo., to reduce the sum total of the expenses incident to President Garfield's illness, there can be no difference of opinion as to the execrable taste of his accompanying remarks, which were characterized by a shameful absence of both decency and veracity. That the faithful, laborious, and self-sacrificing services of such men as Dr. Agnew and Dr. Hamilton, rendered at the urgent request of a sorrowing wife, and in response to the almost imperative demand of members of the Cabinet, should be made the theme for the scurrilous attacks of an ignorant politician, must be a source of regret to all intelligent persons, and we are surprised that Senators, most of whom,

as lawyers, are familiar with the value of the best professional advice, should allow themselves to be influenced by Mr. Vest's cheap rhetoric.

In the light of the elaborate review of the treatment of the late President, which we recently published, it is unnecessary to enter into any refutation of Mr. Vest's invectives, but we must call attention to the crying injustice of speaking of the compensation assigned to the surgeons in attendance as excessive. Their services were in every respect of an extraordinary character, involving an unusual expenditure of time and labor, the assumption of a tremendous responsibility, and involved the neglect of their personal affairs to an extent which was in itself a source of great inconvenience, and of serious loss of professional income. The customary fees of men of their standing and reputation, for single visits to distant cities often equal what the Senate now proposes to award them for weeks of almost exclusive and unremitting attention.

It should be remembered, too, that the duty of the Government in this case is self-imposed, that no claim has been made by these gentlemen for remuneration for the services which they freely rendered in response to the imperative summons from the White House, and that, therefore, no shadow of an excuse has been offered for Mr. Vest's scandalous abuse of them on the floor of the Senate, which has thus far been their only official recompense.

THE NEW SURGEON-GENERAL OF THE ARMY.

UNDER the provisions of the Army bill recently passed, providing for the retirement of officers upon their reaching the age of 64, Surgeon-General Barnes has been retired, and, on the 3d inst., the President nominated Col. Charles H. Crane to fill the vacancy thus created.

Dr. Crane is the son of an army officer, and was born in July, 1825. His appointment as Assistant-Surgeon in the army dates from February, 1848. He first went with troops to Mexico, and at the close of that war was sent to Florida, where he served in the Seminole war. In 1852 he was transferred to the Pacific coast, where he was stationed until 1856, when he was placed on duty in New York, where he remained until the end of 1861. He then became Medical Director in the Department of the South, and so continued until the fall of 1863, when he was placed on duty in the Surgeon-General's office at Washington. At the close of the war, in the organization of the Medical Department, he was made Assistant Surgeon-General, which office he has held to the present time, discharging its duties to the satisfaction of all concerned. The Medical Department of the army is to be congratulated upon the selection for its chief of a gentleman who has been so thoroughly identified with it and who so fully understands its organization and wants.

SURGEON-GENERAL BARNES carries with him into retirement the consciousness of a long and useful official life, and the sincere regard, not only of the Army Medical Corps, but the profession throughout the country.

WE learn with great regret that the appropriation for the National Board of Health, as reported to the House in the Sundry Civil Bill, is insufficient to meet its requirements. Not long since we noticed, with satisfaction, its annual report, and its weekly bulletins have been of the greatest value in spreading a knowledge of sanitary matters of national importance; in co-ordinating our otherwise incoherent sanitary legislation; in publishing researches of great value; and in collecting statistics otherwise unattainable, either at home or abroad. We trust that no such false economy will be carried out, and we earnestly urge our readers to write at once to their representatives and protest against it. The session is nearing its close, and immediate and vigorous action is needed to make our legislators acquainted with the sanitary needs of the country.

As a set-off to the extraordinary cases of pregnancy early in life, we notice that Dr. Kennedy lately presented to the Obstetrical Society of Edinburgh a paper on a case of pregnancy at 62 years of age; Dr. Wilson related one of a married primipara at 49, and Dr. Spence that of a frail maiden who, though not a wife, became a mother for the first time at 50 years of age.

PAWLIK has proposed an ingenious method of exploring the ureters in the female, which, in certain cases, may prove very useful.

Placing the patient in the knee-elbow posture, the vesical triangle is more or less clearly defined on the anterior wall of the vagina, its apex being marked by a slight elevation, and its sides and base respectively by furrows and ridges. The furrows indicate the direction in which the instrument is to be passed, and, by a little searching, the orifice of the ureter may be found and catheterized even beyond the brim of the pelvis. Not only the distance to which the instrument can be introduced is an assurance that we are in the ureter and not the bladder, but we have two others. If in the bladder, the cavity of that viscus allows of free movement, which is not possible if the instrument be caught in the orifice of the ureter, and if the bladder be injected with milk or other colored fluid, the escape of milk or of clear urine by the catheter will give information as to the position of the catheter.

SPECIAL ARTICLE.

OFFICIAL.

REPORT OF THE POST-MORTEM EXAMINATION OF THE BODY OF CHARLES J. GUITEAU,

WHO DIED BY HANGING JUNE 30, 1882, AT THE UNITED STATES JAIL, WASHINGTON, D. C., IN EXECUTION OF JUDICIAL SENTENCE.

THE following physicians were present:

Dr. Noble Young, Physician to the Jail; Dr. A. McWilliam, his assistant; Dr. C. H. Nichols, Supt. Insane Asylum at Bloomingdale, N. Y.; Dr. A. E. McDonald, Supt. Insane Asylum, New York City; Dr. W. W. Godding, Supt. Government Insane Asylum, District of Columbia, and Drs. Witmer and Patterson, his assistants; Dr. Geo. L. Porter, Bridgeport, Ct.; Dr. Johnston Eliot, Washington, D. C.; Dr. D. R. Hagner, Washington, D. C.; Dr. Robert Reyburn, Washington, D. C.; Dr. W. J. Morton, Editor of *Journal of Nervous and Mental Diseases*, New York City; Dr. C. L. Dana, New York City; Dr. C. K. Mills, Philadelphia, Pa.; Dr. D. C. Patterson, Coroner, Washington, D. C.; Dr. J. F. Hartigan, Physician to Coroner; Dr. C. H. A. Kleinschmidt, Washington, D. C.; Dr. P. J. Murphy, Washington, D. C.; Dr. Z. T. Sowers, Washington, D. C.; Dr. F. B. Loring, Eye and Ear Dispensary, Washington, D. C.; Dr. D. S. Lamb, Acting Ass't Surg., U. S. A., and Dr. J. C. McConnell, Microscopist, and Mr. Ernst Schafhirt, Anatomist, Army Medical Museum.

The custodian of the body, Rev. Dr. W. W. Hicks, having requested me to make the examination, and this request being in accordance with one previously made by Dr. Young, I had prepared the following course of procedure, with the object of securing the most exact and satisfactory results: The external appearances of the body should first be noted; the cavities, except the spinal, should be opened and their contents examined; that after the removal of the brain, and its examination without incision, it should be transferred, properly guarded and protected, to the Army Medical Museum, where, through the courtesy of the Curator, Surgeon D. L. Huntington, U. S. Army, it would be photographed and then a cast be taken; that its internal structure should then be observed, and portions set apart for microscopical examination; and that the entire operation should be completed as far as possible the same day, to enable the physicians resident elsewhere, present by invitation, to return promptly to their homes; and that the notes should be taken in duplicate.

Shortly previous to the examination, it was agreed between Rev. Dr. Hicks and the United States District Attorney, Geo. B. Corkhill, that the charge of the removal, preservation, and disposition of the brain should be vested jointly in Drs. Lamb, Sowers, and Hartigan, and that the microscopical examination should be made by parties to be selected by the gentlemen making the agreement.

The examination was then conducted by me, assisted by Drs. Hartigan and Sowers and Mr. Schafhirt, and as near as possible in the order proposed. Drs. Kleinschmidt, Patterson, and others, took notes, and Mr. Charles Trought, of the Museum, the photographs.

By reason of delays, for which neither I nor my assistants were responsible, the examination was not begun until 2.30 P. M. (one hour and a half after death), in consequence of which the photographing was less successful, and a cast was impracticable.

The body, which was of a faint yellowish tint, was that of a man about five feet seven inches in height, and weighed one hundred and forty-five pounds.

The eyes were examined by Dr. Loring, who reported that the pupils were slightly and equally dilated; the vitreous was cloudy, and the fundus indistinguishable. The conjunctiva of the left eye was congested. He repeated the examination two hours later, and noticed an appearance as of transverse fracture of the lenses.

A small white scar, directed obliquely downwards, forwards and to the left, and confined to the scalp, was observed midway between the top of the left ear and median line of the head.

There was a yellowish furrow, a few lines in width, extending around the neck in a direction downwards and forwards, in line of rope. On dissection, the sterno-cleido-mastoid muscles were found to be torn in two, about half way between their points of origin and insertion. The thyro-hyoid ligament was also ruptured, and the hyoid bone and thyroid cartilage widely separated. The large bloodvessels were not injured; neither was there fracture nor dislocation of the vertebræ.

The sexual organs were well developed; the mouth of the urethra was moist.[1] There was also phimosis, on reducing which, a considerable accumulation of smegma was observed.

Skull.—The right parietal bone was slightly flattened over a space about two inches square, just back of the fronto-parietal suture and to the right of the interparietal; there was a slight flattened elevation on the corresponding internal surface of the calvaria. The frontal suture was obliterated, the others quite distinct. A number of Pacchionian depressions were observed near the groove for the longitudinal sinus. In thickness the skull presented nothing remarkable.

Membranes of the Brain.—The dura mater was firmly adherent to the anterior portion of the calvaria in the vicinity of the longitudinal sinus.

There were adhesions of the dura also to the base of the skull; they were quite firm and situated in the several fossæ, and most marked in the deeper parts of the fossæ, where also there were small patches, abruptly limited, of immovable arborescent congestion, with, however, no attendant thickening or pigmentation; this *stagnation* was again most marked in the left anterior and middle fossæ. There was no congestion of the dura except at the points just noted.

The dura and pia mater were adherent to each

[1] During the suspension of the body, erection of the penis took place, and the clothing was afterwards found to be moist.

other and to the brain on both sides along a limited portion of the longitudinal fissure in the vicinity of Pacchionian granulations.

The dura was slightly thickened along the longitudinal sinus. It was also slightly thickened and opaque along a portion of the line of the middle meningeal artery on each side.

The arachnoid of the upper convexity of the brain presented in many places, where it covered the sulci, small patches of thickening and opacity; elsewhere it was normal.

The pia mater was anæmic anteriorly; posteriorly there was slight hypostasis.

The cerebral vessels appeared to be normal in all respects.

The orbital plates were well arched, and presented many conical eminences of large size. There was no roughening anywhere of the inner surface of the skull.

The brain was firm. Its weight, including the cerebrum, cerebellum, pons and medulla, and a portion of the dura, was 49½ ounces. It was slightly flattened in the region corresponding to the flattening of the parietal bone above mentioned. On section of the cerebrum there was an appearance as of slight thinning of the gray cortex; the measurements taken, however, gave depths of $\frac{1}{16}$ to $\frac{1}{8}$ inch in close proximity to each other. The white substance was almost absolutely anæmic. The cerebellum and island of Reil were both *covered* on each side.

on the left side, except that the fissure was crossed by a small bridge near its centre. The second and third frontal fissures presented nothing remarkable. There were numerous secondary fissures.

The præcentral and retrocentral fissures, on each side, were well defined, and were unconnected with other fissures. The inter-parietal fissure, on each side, terminated in the transverse occipital, separated only by a slight bridge. The parieto-occipital was well marked on each side. The transverse occipital fissure on the right side was ill defined; it began on the median surface and extended well outwards. The first temporal fissure was well developed on the right side; on the left, was not of the usual length. Wernicke's fissure was well marked on the left side, but not confluent.

The calloso-marginal fissure was double on each side; the upper of the two being probably the true one. On the right, the upper one extended back to the anterior margin of the paracentral lobule; on the left, not quite so far. The lower one extended on the right side to a line about half an inch in front of the parieto-occipital fissure, from which it was separated by a small bridge; on the left side, also, by a bridge of larger size.

Orbital Surface.—On the right side were seven fissures radiating from a circular fissure surrounding a small isolated convolution; on the left side were five fissures radiating from a small shallow depression. The left collateral fissure was well defined, extending to the anterior extremity of the tem-

Upper and anterior view of the brain, in which also a portion of the dura mater appears.

The Fissures.—The fissures generally presented a considerable depth; in many places, as in the right fissure of Rolando, amounting to ⅞ inch.

The right fissure of Sylvius was typical; the left was separated from the first temporal fissure by a slight bridge deeply situated. The right fissure of Rolando did not connect with the fissure of Sylvius; the left was separated only by a small bridge deeply situated. Both were separated from the longitudinal fissure.

The first frontal fissure on the right side was not connected with that of Rolando, but at the posterior part was crossed by a secondary fissure. The same

poral lobe; the right was also well marked, but did not extend so far back as the other, and there was an attempt at confluence anteriorly with the temporo-occipital, a small bridge intervening. The left temporo-occipital fissure was well defined.

The Convolutions.—The following alone call for remark: The ascending frontal was well defined on each side.

The ascending parietal on the right side was well developed in its lower three-fourths, but narrowed in the upper fourth. On the left side the narrowing was less marked. The island of Reil presented on the right side five fissures and six straight gyri; on

the left side, seven fissures and eight straight gyri. The paracentral lobule was well marked on the right side; small on the left.

The accompanying drawing of the brain is from a photograph taken four hours after death.

Thorax and Abdomen.—The usual median incision was made, and the abdomen opened. There was an extravasation of blood into the right pectoralis major muscle near the second rib. The adipose layer of the abdominal section was one inch in thickness. The dome of the diaphragm extended up to the fourth rib on each side.

There were old pleuritic adhesions at the apex of the right lung; the upper and middle lobes were congenitally united by connective tissue. The lung was normal throughout. There were also old pleuritic adhesions of the left lung to the diaphragm and between its lobes; three small tubercle-like, pigmented patches were observed in the upper lobe. The heart weighed ten and three-quarter ounces; its muscular substance was apparently normal. There was an abundance of fat upon its anterior surface and a villous patch of old pericarditis near the apex of the left ventricle. The right ventricle contained a little blood just forming a clot.[1] The valves were normal. The aorta was slightly atheromatous for a short distance above the valves.

All of the abdominal viscera presented large accumulations of fat. They were normally situated. The liver was congested; the gall-bladder contained a little bile; the spleen was lobulated and enlarged; it weighed eighteen ounces; the capsule was bluish, the substance brown; the Malpighian bodies hypertrophied;[2] the pancreas was normal; the stomach contained food;[3] the intestines appeared normal, were not opened; the kidneys were congested; there was a small superficial serous cyst on the right one. The bladder contained a considerable quantity of urine.

The results of the microscopic examinations will be reported hereafter.

D. S. LAMB.

Army Medical Museum, Washington, D. C.,
July 4th, 1882.

SOCIETY PROCEEDINGS.

OHIO STATE MEDICAL SOCIETY.

Thirty-seventh Annual Session, held at Columbus, June 13, 14, and 15, 1882.

(Specially reported for The Medical News.)

Tuesday, June 13.—The Society was called to order by the President, Dr. Starling Loving, of Columbus.

Dr. H. G. Landis, of Columbus, read a paper on

THE PROGRESS OF OBSTETRICS AND GYNECOLOGY.

He first discussed the use of anæsthetics in labor, and condemned the practice upon the following grounds: 1. Labor is not normally attended with much pain. 2. The duration of labor is normally brief. 3. If labor is either painful or long, it is due to pathological conditions which the physician should discover and remove, instead of smothering the evidences of their existence by anæsthetics. Credé's method of extracting the placenta was warmly advocated as the best method of averting *post-partum* hemorrhage and all other puerperal complications. Antiseptic midwifery was briefly discussed, with quotation of the views of Barnes. Lacerations of the perineum and cervix during labor were treated of, the author recommending a conservative course, having doubts as to the necessity for frequent operations, especially in the latter class of cases. He thought lacerations would be less frequent if care were taken to extract the head during the absence of pains, while womb and woman were passive.

Dr. D. N. Kinsman, of Columbus, read a lengthy paper on the

ETIOLOGY OF CONSUMPTION.

According to Jaccoud, consumption is hereditary, inborn, or acquired. Heredity and acquisition only were treated of in this paper, in which the writer maintained the direct transmission of the disease, as well as the transmission of a morbid tendency toward it. The second point was supported by the citation of many cases where there seemed to be strong evidence that the disease was communicated by aerial contagion. Contagion from food was inferred as possible. Perlsucht, or bovine tuberculosis, is a disease distinct from human tuberculosis. The same form of tuberculosis affects cattle as the human subject; hence the consideration of tuberculosis in cattle becomes of importance to public health. The paper was illustrated by microscopic drawings from specimens of tuberculous lungs, which were used to enforce the distinction between catarrhal pneumonia and caseous or tuberculous pneumonia, when the stage of consolidation of the lung is reached.

In the discussion, Dr. J. H. Pooley, of Columbus, stated that he thought that the paper was not a theoretical one, but one of practical value. He had for a long time been convinced that phthisis was, under certain circumstances, contagious, and related a confirmatory case. He questioned the writer's statement that, because consumption is contagious, it cannot therefore originate *de novo;* chancroid is contagious, but it certainly can originate *de novo*, through filth, promiscuous intercourse, etc.

In response to a question, the author stated that the period of incubation would depend upon attendant circumstances in each case.

Dr. Reuben A. Vance, of Cleveland, read a paper on the

SURGERY OF THE ARTERIES,

in which he traced the distinction between disease of the arterial walls and wounds of arteries, showing the influence of the sac in the one case, and the results of extravasation of blood in the other, and objected to applying to the two the common name of "aneurism." He described nature's methods of curing aneurism by depositing layers of fibrin on the walls of the sac until the sac, or even the calibre of the artery, is obliterated. In some cases a layer of this fibrin becomes detached, and blocks up the efferent artery, when coagulation occurs, resulting in cure. Or, finally, inflammation and suppuration may set in, destroying the tumor, but generally killing the patient. In treatment, the force of the circulation need be but slightly diminished to induce a tendency to the deposit of these layers. This may be brought about by rest, position, pressure, or compression. Electro-puncture, the "old operation," manipulation and ligation, or torsion, are more radical means. The operations of Anel, Hunter, Brasdor, Wardrop, and Syme, were reviewed and compared.

[1] A considerable quantity of dark blood ran out of the heart in the separation of the heart and lungs.

[2] Dr. Young states that the man was subject to malarial attacks while in the jail.

[3] He had eaten a dinner about an hour and a half before the execution.

The fact that secondary hemorrhage frequently occurs from the end of the artery, beyond the ligature, was shown to depend upon nature's failure to properly seal it. Of radical operations for aneurism, Hunter's is undoubtedly the surgeon's choice—the distal operations being those of necessity.

After detailing the treatment of most cases of so-called false aneurism, the author found three classes of cases in which opinions differ as to the best course to be pursued, viz.: 1. Where a pulsating tumor forms about a wounded vessel, after, perhaps, the surface incision has healed. 2. Where blood has accumulated, and still accumulates, in the tissues about a wounded artery, external hemorrhage having ceased. 3. Where an enormous amount of blood distends the parts about a wounded artery. Dr. Vance held that in these cases, if rest, position, pressure, and compression failed to cure, the surgeon should cut down, turn out clots, and ligate above and below the seat of the injury. By so doing, he ligates no more than is essential, perhaps only a branch instead of a main trunk. He summed up as follows:

1. Bleeding from an accessible artery should be checked by twisting or tying both ends of the vessel. 2. Moderate hemorrhage from one not readily reached, should be controlled by rest, position, local pressure, compression, etc. 3. Severe hemorrhage from an artery, not controllable by pressure, etc., requires that the vessel be sought in the wound and both ends tied or twisted. (a.) An exception was noted in certain wounds of the hand or foot, where the danger of damaging important structures is great; here the ligation of femoral or brachial, with pressure, was advised. 4. In fractures complicated by wound or rupture of a large artery, the surgeon should at once cut into the swelling, turn out the clots, and twist or tie both ends of the vessel. 5. In pulsating tumors, following wounds or injuries of arteries, should rest, etc., fail, the tumor should be opened, clots removed, and the vessel tied or twisted above and below the lesion. 6. When a wound or injury of an artery has led to extravasation, no operation should be performed so long as rest, etc., can restrain further hemorrhage. (a.) An exception is to be noted where the extravasation is so great as to threaten gangrene, or where, after checking further increase, the above measures fail to reduce the size of the tumor. 7. If the extravasation caused by arterial wound or injury cannot be held in check and further hemorrhage prevented by position, etc., the tumor should be at once cut open, the clots removed, and the vessel tied or twisted, above and below the point of injury.

DR. D. HALDERMAN, of Columbus, thought the writer had failed to impress the treatment of diffused aneurisms, or traumatic aneurisms, where it was necessary to cut into the tumor and ligate both ends of the artery—Syme's operation. He thought one great danger in this operation lay in the risk of wounding the accompanying veins. Several years ago he had one of these cases, involving the point of termination of the femoral in the popliteal, in which he made the Hunterian operation successfully. The man is alive yet, but has a small tumor.

DR. J. H. POOLEY said that every surgeon should have a well-defined plan for meeting all emergencies, and aneurism belonged in this category, at least in this country. He did not quite see the pertinence of the criticism of the present nomenclature: "false aneurism" conveys a definite meaning, and is well enough retained. He believed in Mr. Guthrie's axiom, "Tie both ends of the artery," when possible. Syme's operation—the so-called "old" operation—is an operation of necessity, not of choice. Thought ordinary care and prudence would prevent injury to the veins. Did not think there was much new, or could be much new, in the surgery of the arteries since the days of Hunter.

EVENING SESSION.—This was occupied by a lecture by PROF. EDWARD ORTON (late President), of the Ohio State University, on

THE RELATION OF THE STATE TO PUBLIC HEALTH.

The lecturer took for his text Franklin's aphorism, "Public health is public wealth," and also Disraeli's statement, that "the health of the people is the first duty of the statesman." He first spoke of the loss to the State of sickness, especially of epidemics, referring to the estimated loss of Philadelphia, during the small-pox epidemic of 1871-2, of $24,000,000. With individual cases of sickness the State can have no concern, but in epidemics its power to act is universally conceded.

The lecturer sketched the growth of sanitary measures from the time of Moses, Plato, and Hippocrates, to the present, showing that during the fearful pestilences of the Dark Ages, "The curse causeless did not come." He thought the time was near at hand, which Dr. Benjamin Rush predicted, "when our courts of law shall punish cities and villages for permitting any of the sources of bilious and malignant fevers to exist within their jurisdiction.

He entered a plea for *system* in the making of public sanitary improvements, and protested against the work being undertaken by fickle-minded, temporary, and changing municipal boards. The work must be planned by a competent civil engineer. He spoke of a trunk sewer, "in a principal street in a great city, that, like a gorged serpent, was larger in the middle than at either end;" of others many times too large for any possible demand, which thus became mere reeking cesspools; and, worse still, of others built in villages, for general purposes, before a water supply had been secured or even thought of.

He next spoke of the pollution of rivers, and the necessity of laws for their protection. No city thinks of those that live below it, the practical doctrine being, "the devil take the lowermost;" and he quoted with effect Coleridge's lines—

> "The river Rhine, as is well known,
> Washes the city of Cologne;
> But, Oh! Ye gods and powers divine,
> What then shall wash the river Rhine?"

He closed with a line of argument showing the importance of and necessity for a State Board of Health.

WEDNESDAY, JUNE 14.

MORNING SESSION.—W. T. COELETT, M.D., L.R.C.P. London, of Cleveland, read a paper on the

ETIOLOGY OF CERTAIN CUTANEOUS AFFECTIONS.

Eczema he regarded as "a superficial dermatitis due to an *irritation* of the sensitive filaments of the peripheral nerves," the origin of this irritation being either external, *i. e.*, local, or internal, *i. e.*, constitutional. Psoriasis he thought was a local disease.

DR. N. P. DANDRIDGE, of Cincinnati, read a lengthy report on the progress in

SURGICAL DISEASES OF THE GENITO-URINARY ORGANS.

He spoke quite at length of prostatic diseases and of Bigelow's operation.

DR. VANCE said he would not exalt Bigelow's operation, perhaps, as highly as the writer, but he regarded it as a good operation. The operation itself was, however, but the natural outgrowth of the operations that preceded it.

DR. A. C. MILLER, of Cleveland, thought that enlargement of the prostate was of more real importance than all the other troubles described. Prostatorrhea, or chronic gleet, is due to a diseased gland, and its treatment by injections borders on malpractice, as liable to result in stricture or abscess.

Dr. P. S. Conner, of Cincinnati, said that cutting succeeded so well, that, for himself, he did not care to change to crushing under ordinary circumstances. If he had a stone in his own bladder, he would prefer to be cut. Better results follow; he once saw an autopsy at which eight calculi were removed from a man's bladder, in whom lithotripsy had been performed seven times. Cutting would have removed all these at once. He preferred rapid crushing to slow, but no one should attempt the operation until perfectly familiar with the instrument. For inflammation of the prostate, he recommended *hot* water rectal injections, by means of a double canula, or even an ordinary syringe, the stream being directed against the anterior wall of the rectum.

Dr. S. C. Dumm, of Constantia, spoke favorably of electricity for hyperæsthesia of the urethra.

Dr. P. S. Conner, of Cincinnati, read a paper on

EXTERNAL PERINEAL URETHROTOMY,

in which he highly recommended the operation in cases of deep, impassable strictures.

Dr. J. H. Pooley said that external perineal urethrotomy was his favorite operation, and he was glad the writer advised it. The doctrine that "where water can come out, a bougie can go in," is not true either in theory or practice, and after failure with bougies the knife is the best means of relief and cure.

Dr. Vance said there was much to be said in favor of the operation advocated, but he preferred the internal operation. In the great majority of cases, a single filiform can be passed; by letting this remain for twenty-four hours, a No. 6 or No. 10 can be passed, and then internal urethrotomy can be performed, with a better result than that obtained by the external incision.

Dr. W. J. Scott, of Cleveland, said he had several times failed with filiform bougies, but when cut down he ordinarily had little trouble. In these cases he adopted the following method: pass a sound, of fair size, *to* the stricture; cut down, taking care to make an incision *smaller* than the end of the sound: withdraw the sound a short distance, and then with a small probe, working through the incision, find the passage, follow the probe with a director and then use the knife. Pass a catheter, which is to be left in for some hours, until inflammatory deposits are thrown out so as to correct the curvatures. He had never failed with this method.

Dr. Sidney Norton, Professor of Chemistry in the State University, read a paper on the

CONTAMINATIONS OF DRINKING WATER.

No drinking water is chemically pure. The impurities, however, are not harmful if they consist of mineral matters, like clay or sand, which soon subside, or of fresh organic matters, vegetable or animal. Neither are the lime salts nor the alkalies harmful, unless in excess. The popular taste prefers a water of this sort. Neither is water harmful if it contain the final products of organic decomposition, viz., carbonic acid, ammonia, and the oxides of nitrogen, unless in large amount. But all decomposing organic matters are dangerous. One part in 1,000,000 will render water dangerous, as it may contain soluble and organized ferments, capable of multiplying a thousand-fold in a short time, and of inducing zymotic diseases. The writer accepted the conclusions of the London Board of Water Supply, that running waters are self-purifying, as are also those of deep wells and perennial springs.

Afternoon Session.—The following is the result of the

ELECTION OF OFFICERS.

President.—C. P. Landon, M.D., of Westerville.

Vice-Presidents.—Drs. E. Sinnett, A. C. Miller, N. Gay, W. B. Hedges.

Secretary.—Geo. A. Collamore, M.D., of Toledo.

Treasurer.—T. W. Jones, M.D., of Columbus.

Dr. Starling Loving, of Columbus, then delivered the

PRESIDENT'S ADDRESS.

He recommended a fixed place of meeting, which would naturally be at Columbus, where could be erected a suitable building for meetings, and a library and museum founded. The Code of Ethics was then considered, and the opinion was expressed that when we consent to associate professionally with irregulars we shall not elevate but, on the contrary, degrade ourselves from the high position we have always occupied, to the level of a mere trade, for most of them use their name as a trade-mark only, and appreciate fully that it comprises their sole claim upon the public.

Of course, if we modify our Code so as to permit fraternization, however limited, with homœopathists, we shall be obliged to extend the same courtesy to eclectics, spiritualists, uroscopists, *et id genus omne*, including Lydia Pinkham and the "retired clergyman whose sands of life have nearly run out," for, in the language of the surgeons, the line of demarcation is not very broad. The thought is not overly pleasant! It might be more so if what was done by the New York Society had been accepted as a concession and an expression of good will, but it was not .The homœopathic journals claim it as a great victory for their side, and as evidence that the regular profession is trembling for existence.

Finally, if we go with the New York Society, or, rather, the minority of that Society who changed the Code to suit themselves, we must consent to be dropped, like those gentlemen, from the fellowship of our own profession. This morning, in adopting your new Constitution, embracing the Code of the Association, you declared against it. The thing is impossible. The American Medical Association, our Supreme Court, has unanimously declared against it.

The evils arising from the increasing use of non-officinal and proprietary medicines, were noticed, and the methods of introduction, by seductive samples and equally seductive agents, graphically described. The growing use of such remedies was deprecated.

The failure of the Board of Health bill to pass was deeply deplored, and the importance of the measure insisted upon. In this connection the speaker referred to the poorly constructed and illy-ventilated State buildings, including the school-houses, which are so badly arranged in these particulars that myopia is rapidly increasing. He also spoke of the necessity of supervision in the location of towns, with their water supply and sewerage; of the adulteration of food; of protection against epidemics; of vital statistics, and of other matters properly coming under the control of a Board of Health.

In case of failure in establishing such a board, it was recommended that an attempt be made to have the State create a Board of Censors, to examine all who propose to practice, and "to stand between the people and the medical colleges." If both these plans fail, then the members of the Society should refuse to receive incompetent men as students.

The Address, though long, was listened to with the closest attention throughout.

Dr. S. C. Ayres, of Cincinnati, read a paper on

RETINITIS ALBUMINURICA.

After some general remarks, he referred to the comparative frequency of retinitis in cases of albuminuria. In 104 cases of albuminuria in the Cincinnati Hospital, during 1877, '78, '79, there were ten cases, or 9.6 per cent., of retinitis. Of these, five died, two were discharged improved, and three unimproved. He described the typical ophthalmoscopic appearance of the

fundus, and called attention to the necessity of the frequent use of the test-tube and microscope. He stated that nephritic retinitis occurred most frequently in cases of small granular or contracting kidney.

DR. PHILIP ZENNER, of Cincinnati, reported a *Case of Hemiplegia: Secondary Degeneration of the Pyramidal Tracts.*

DR. W. H. MUSSEY, of Cincinnati, next described the *Treatment of Chronic Cystitis by a Curette*, designed by himself for scraping the surface of the bladder.

The same gentleman also reported a case of *Removal of Astragalus for Necrosis*, in which his patient made an excellent recovery.

EVENING SESSION.—DR. J. R. BLACK, of Newark, delivered a popular lecture in the chapel of the Deaf-Mute Asylum, on *Preventing Diseases*, after which the members and invited guests partook of a banquet furnished them by the trustees of the institution.

THIRD DAY.

MORNING SESSION.—DR. G. S. FRANKLIN, of Chillicothe, read a paper on *Public Charity and the Medical Profession.* In this he dwelt especially on the defective and unjust laws in Ohio, relating to the care and medical treatment of the township poor.

DR. E. B. PRATT, of Mt. Sterling, read an exhaustive paper on the treatment of some of the more common forms of *Inflammation of the Knee-joint.* In acute inflammation he recommended rest, secured by Buck's extension apparatus, abstraction of blood locally, by leeches, cups, or incisions, diminishing the supply of blood by compressing the femoral with a sponge, cold, pressure by bandaging the joint over sponge. For erosion of the cartilages, use the actual cautery. After the acute stage has subsided, Sayre's knee-joint splint may be applied, so that the patient may be able to take exercise. Constitutional treatment from the outset, as needed. For the effusion, aspiration may be resorted to if necessary, but it should not be done merely for relief of pain, unless all other means fail. It will not shorten the acute stage. It should not be used when the effusion is purulent; the cartilages or bone being necrosed, make a free incision. It should be resorted to when the acute stage begins to subside, usually during the fourth week. For sub-acute inflammation use Sayre's splint, iodine, the rubber bandage, aspiration. Chronic inflammation requires extension, the cautery, pressure, thorough drainage, removal of necrosed tissue, anchylosis in straight position—if motion is despaired of, and lastly, excision or amputation. Medicated injections into the joint are apt to do more harm than good, and Listerism is not recommended.

DR. POOLEY strongly recommended irrigation by cold water through rubber tubing. Thought pain from effusion an indication for aspiration. For pressure, preferred adhesive straps. Proper classification would be into those cases involving the synovial membrane, and those affecting the bone. The latter are generally tubercular, and essentially chronic. Should be treated by plaster-of-Paris splint; put a thick sole on foot of sound limb, furnish the patient with crutches, and make him exercise. Amputation is safer and better than excision. It is not true that any sort of a leg is better than an artificial one.

DR. HAMILTON thought aspiration might be regarded as a curative measure, in acute synovitis, and related a case. Irrigation by tubing is efficient, but laborious and requiring attention. Advised extension to overcome flexion, and fixation by plaster.

DR. GARRISON, of Utica, while sanctioning all that had been said, recommended *hot* water to reduce the inflammatory action.

DR. MUSSEY, of Cincinnati, preferred Day's posterior splint. Leave joint exposed, and apply cold water or leeches. Aspirate, or open joint with knife by valvular incision. If the limb is to be elevated, the surgeon must remember to slightly flex the leg, else the joint will be pinched,

DR. W. MORROW BEACH, of London, read a paper on *Achievements and Failures in Medical Art.*

DR. W. B. DAVIS, of Cincinnati, read a report on the

PROGRESS OF MATERIA MEDICA AND THERAPEUTICS.

Therapeutics was formerly based entirely upon experience; hence many of the triumphs of medical treatment in the past we now know were mere coincidences. Progress in therapeutics, like progress in the practice of medicine, must be based on a knowledge of anatomy, physiology, pathology, and chemistry. To discover errors is to make progress. Modern therapeutics has done this, and in addition our knowledge of the physiological action of quite a number of drugs is now firmly established. Progress in this direction has been so rapid of late that even the present generation of physicians may live to see many of our present empirical methods of treatment supplanted by others founded on the solid rock of science.

DR. JOSEPH EICHBERG, of Cincinnati, read a report on the

PROGRESS OF LARYNGOLOGY.

Two topics were embraced in this report, viz., the pathology of laryngeal phthisis and the identity of croup and diphtheria. The importance of early diagnosis was mentioned, and the means of making it by laryngoscopic examination described. Tubercular disease of the larynx may often be regarded as primary, simply because of our inability to recognize the early deposit of tubercle in the lungs.

The writer maintained the identity of croup and diphtheria, claiming that both the pathological and clinical features bear out such a view. He attempted to reconcile the differences seemingly existing between the two, and to show that they often bear the same relation to each other as do the mild and severe cases of an epidemic of any acute infectious disease, the differences in the symptoms being dependent upon differences in function of the parts involved.

DR. GEO. W. GARRISON, of Utica, read a report on

CANCER.

He thought cancer was the result usually of a local injury, and he denied its hereditary transmission. It may appear at any age, but is most apt to attack the tissues at the time when they are undergoing degenerative changes. Cancer cells cannot be differentiated from constructive cells; the caudate cell does not necessarily imply malignancy. As to treatment, he has found escharotics to give very favorable results in 35 cases.

DR. GEO. A. COLLAMORE, of Toledo, read a report on

PROGRESS OF MEDICINE.

He spoke of the experiments of Pasteur and their important relation to medicine; of Koch's supposed discovery; of pyrexia; of the treatment of scarlet fever and diphtheria; and of the salicyl compounds in rheumatism.

DR. A. M. BLEILE, of Columbus, read a paper on

DIGESTION.

This paper was based largely on original experiments. He condemned any attempt at using *ptyalin* in medicine, as its action is rendered *nil* in the stomach. Pepsin does little good in dyspepsia unless accompanied by hydrochloric acid, or bismuth, which latter acts as a local stimulus. Pancreatic ferment is destroyed when taken into the stomach, hence it is useless as a remedy.

It being now late in the afternoon of the third day, the remaining papers were referred to the Publication Committee, and the Society adjourned, to meet in Cleveland next year, at the time of the meeting of the American Medical Association.

TRANSACTIONS OF THE OBSTETRICAL SOCIETY OF PHILADELPHIA.

Stated Meeting, June 1, 1882.

The President, Edward L. Duer, M.D., in the Chair.

Dr. B. F. Baer related the history of a case of *Punctured Wound of the Pregnant Uterus; Partial Escape of the Fœtus into the Abdominal Cavity; Retention of the Fœtus Five Years.*

October 4, 1881, Catherine Curley presented herself at the Dispensary for Diseases of Women at the Hospital of the University of Pennsylvania, and gave a history which is essentially embodied in the following letter from her physician, Dr. John Keogh, of Killaloe, Ireland. (This letter was received after the patient had been treated as described in this paper, but as it gives an intelligent description of the case at the time of the accident, it was thought proper to insert it here.)

"Catherine Curley, who was within a week of her confinement, was standing upon a chair, the back of which, with the exception of two uprights, had been broken away. She was at the time collecting brambles, and in stretching for one over-reached herself and fell, and in the act of falling her right side came in contact with one of the uprights. A short time after she was found lying on the ground in a fainting condition, from which position she was removed to bed and I was summoned to see her. On examination I found a contused wound on the lower and right side of the abdomen, and in addition came to the conclusion that the womb was ruptured and that the fœtus had escaped into the cavity of the abdomen. There was intense tenderness and great distention. I immediately decided on giving her at once calomel and opium—the latter in large doses. After the third day I stopped the calomel and continued the opium. The pain and tenderness almost disappeared after a week, and I may say from that period until she left here she never had a bad symptom."

"Several medical men in this county expressed doubt about the correctness of my diagnosis, but I at once convinced them by presenting the woman for examination at Limerick, a city near here, where many men of eminence and long experience saw her."

Dr. Keogh does not mention that the prong of the chair was driven into the abdomen, rupturing everything before it except the skin, which, on account of its great strength and elasticity, escaped unbroken.

It would seem incredible that the pain and tenderness should have almost disappeared in a week, and that she should not have had a bad symptom until five years had elapsed. She, however, recovered from the accident and, strange to say, menstruated three months afterwards and has been doing so regularly ever since. To make matters worse, if possible, her husband, who was in the last stage of phthisis at the time, died within a week, and she was left without means to support a family of five small children. This she did through four years by manual labor. Three years ago she came to this country and settled in Salem, N. J., where last summer she was under the care of Dr. E. S. Sharp, at which time she passed through an attack of what seemed to be typho-malarial fever, in consequence of which she became somewhat emaciated, and her muscles became relaxed and toneless. This allowed a hernial protrusion through the puncture in the abdominal wall; for this she sought relief, hoping to procure a suitable truss. I only obtained the history of the accident by direct questions in regard to the cause of the hernia, that being regarded by the patient as the greater difficulty and the one requiring treatment. Physical examination with the patient in the dorsal position revealed, by palpation of the abdomen, a circumscribed mass in the hypogastric region, extending as high up as the umbilicus, and a little farther to the left than to the right of the median line. It was about the size of the pregnant uterus at the sixth month, rather flaccid, and pressure on it gave to the hand the sensation of loose bones moving over each other—a kind of crepitus. On the right side of the abdomen, a little below the umbilicus, there was a round perforation, about the size of a silver dollar, which seemed to penetrate everything except the skin. Through this break in the abdominal wall the intestines protruded when she was upon her feet, constituting the ventral hernia for which she desired the truss. Examination *per vaginam* gave the following result: The cervix uteri was small, hard, rather low down, and pointing forwards in the direction of the vaginal orifice. The os externum was small and circular, but it was patulous, and flowing from it was a peculiar yellowish fluid, slightly fetid. The finger, carried posterior to the cervix, discovered the body of the uterus enlarged, and apparently expanded around the loose bones referred to above. Now, carrying the finger to the anterior surface of the cervix, the same bulging forward was discovered, and the same continuation of the anterior wall of the cervix into what appeared to be the anterior wall of the developed uterus. Bimanual examination seemed to confirm the opinion already formed that the fœtal remains were still, in part at least, within the uterine cavity. On the right side of the uterus, near the fundus, there was a prominence; otherwise the walls were smooth. I now passed the sound through the os and into the uterine cavity, when it came upon a mass of bones which seemed to be loosely held together by disintegrating soft tissues. The instrument was readily passed to a depth of six inches, and could be moved about with the greatest ease, and without the least sensation of pain to the patient. Its withdrawal was not followed by any discharge. There was nothing about the case which led me to suspect even that the sound had not really passed into the uterine cavity, but, instead, that it might have passed through an opening in the uterine wall, near the cervix, into an extra-uterine cyst containing the fœtal remains. It may, however, have passed through the opening which was afterwards found near the fundus, but not before meeting with that portion of the remains surrounded by the expanded but flaccid uterine walls.

I was naturally, I think, rather inclined to disbelieve the history of rupture of the uterus, from such an accident, to a degree sufficient to allow the child to escape into the abdominal cavity, since the subject was alive and before me. I sought to explain the unusual condition by one of the following hypotheses, viz.: *First*, that the pregnancy had been an extra-uterine one and probably of the interstitial variety; that the accident resulted in the death of the child merely, and not in rupture of the gestation sac; that it then remained a harmless body until the patient had become reduced by the fever noted above, when it began to disintegrate from decomposition and be thrown off *per vaginam*, after first ulcerating its way through the uterine wall into the cavity of the uterus; but this could not have been so and the physical condition set down as the result of my examination exist. *Second*, that it was one of those very rare cases of so-called missed labor in which, for some reason, shock of an accident for instance, by which the nervous system is so depressed

that there is not power enough to cause uterine contraction, the product is retained indefinitely within the cavity of the uterus. *Third* (and considered the correct explanation), that the uterus was really ruptured, but that a portion only of the child escaped through the rent, thus preventing by pressure a loss of blood which would otherwise have probably resulted in the death of the patient, and that the portion which projected through the rupture became encysted, thus forming a cavity continuous with the uterine cavity, the whole mass remaining harmless until through the intercurrence of an exhausting disease, decomposition set in, and it began to poison the patient. It is not necessary to offer an explanation, if the latter hypothesis be correct, why the uterus did not contract and expel its contents, because it is well known that in the event of a rupture occurring during labor the pains immediately cease. But in any event expulsion could not have been accomplished here with the child held fast in the rent. Then, I think, the fact that the patient came so readily out of the collapse and recovered so quickly, and that the child lived so long (it is said to have lived three days), prove pretty conclusively that there was no great blood loss, and that the child did not escape entirely from the cavity of the uterus. The child dies very soon after it is expelled into the abdominal cavity for two reasons, viz., maternal hemorrhage, and interference with the function of the placenta and cord. Hemorrhage did not occur, if my theory is correct, for the reason stated above, and the functions of the placenta were not interfered with at once because it was not separated from the uterine wall suddenly, nor compressed as would have been the case had the uterus been empty and contracted.

My advice to the patient was that she submit to an operation for the removal of the decomposing mass, as I considered that she was suffering from slow septic absorption. The operation I suggested was dilatation of the os uteri and removal of the dead product *per vias naturales*. This I looked upon as the most feasible operation, for the reason that it seemed to be of such easy access through that channel, and therefore the one which would be attended by the least amount of danger. Removal by laparotomy would have been most hazardous, since it would have been necessary to open the cyst, and therefore the old rupture of the uterus. There would then have been a fistulous opening in the uterine wall, which would probably have been closed with difficulty, if at all. Moreover, the sac would very likely have ruptured, thus precipitating the contents into the peritoneal cavity. This, of course, would have been a grave complication, as the decomposing material would have been removed with difficulty and danger. Against removal through the os uteri was the possibility, if not probability, of rupture of the sac containing that portion of the fœtus outside the uterus and expulsion of the contents into the abdominal cavity. This might have necessitated laparotomy for the cleansing of the peritoneal cavity. The patient, however, refused at that time to have the operation performed, and returned to her home.

December 16, 1881, she again presented herself at the dispensary, and exhibited undoubted evidence of septic absorption in rapid pulse, evening rise of temperature, and night-sweats. Examination now showed the mass to be much lower in the hypogastrium, and apparently smaller than at the previous examination. The cervix was, however, of the same length and still hard, with no tendency towards dilatation of the os. The sound revealed the dead product to be nearer the os, and altogether this examination served to confirm my former opinion that the product was largely contained within the uterine cavity, and that it could be removed through the os and vagina. This opinion was strengthened by the fact that there had been evident contraction of the walls surrounding the mass. She still refused to submit to the operation, and returned to her home. Her health continued to depreciate, and she was glad, on January 3, 1882, to enter the gynecological ward of the Hospital of the University, in charge of Dr. Goodell.

After careful examination, Dr. Goodell confirmed, in the main, the opinion expressed above as to diagnosis and treatment, and two days later introduced into the os uteri one sponge and four laminaria tents. Next day the patient was anæsthetized and the tents removed, when an effort was made to remove the fœtus. A fenestrated polypus forceps was passed into the cavity and made to grasp the contents; this was readily done, but the removal was not so easily accomplished, for when traction was made it was found that the fœtus was held firmly somewhere, and that it was so disintegrated that only the portion within the grasp of the forceps could be withdrawn with the instrument. This was repeated a number of times, each withdrawal of the forceps bringing away a bone or some broken-down soft tissue. A discharge of about a pint of very fetid thin fluid took place at this stage of the operation. The os was now becoming so small from contraction of the cervix that the forceps could scarcely be made to pass, and an effort was made to secure further dilatation by the use of Molesworth's dilator. But it would not work, because it was out of order from long disuse. The only thing left to do was either to introduce another set of tents and wait until they had dilated the cervix sufficiently, or incise the neck to the vaginal junction. The latter was done. The danger of septic absorption from such a proceeding was fully considered, but it was decided that to introduce another set of tents, let the patient come out of anæsthesia and wait for their slow dilatation would be the greater evil. Before and after the incision, the parts were thoroughly disinfected by injections of a permanganate of potash solution. The same polypus forceps were now more readily introduced into the cavity and the mass broken up. This was followed by a profuse, thin, bloody, purulent discharge of the most fetid character. An injection of the permanganate solution was now made into the cavity of the uterus until it returned unchanged, when another effort was made to remove the contents. After working for more than half an hour, only a part of the product was withdrawn. At this stage of the operation considerable hemorrhage occurred, and this was increased with each endeavor to dislodge the mass from its nidus. For this reason, and because the patient was becoming weak (she had now been under ether one and a half hours), it was thought prudent to discontinue further efforts for the present, and to depend upon antiseptic injections and contraction of the uterus to remove the remainder, or, at least, to allow the patient to recover from this desperate condition and gain strength to stand a second effort after the mass had undergone further disintegration. There was also a fear of rupturing the cyst containing that portion outside of the uterine cavity by further efforts.

The patient came out of the anæsthesia slowly, and in a state bordering on collapse, in which condition she remained for nearly twenty-four hours, when she gradually reacted. During the next four days there was a very fetid fluid discharged from the cavity of the uterus, together with some débris from the decomposing mass. The patient had to be removed from the ward on account of the odor. The treatment was supporting, with very frequent irrigation of the vagina and uterine cavity with antiseptic solutions.

On the fifth day after the first operation, the patient evidently suffering from septicæmia, and there being

no marked effort on the part of the uterus to throw off the remains, she was again etherized, and another attempt was made to remove them. It was found that time had somewhat disintegrated the contents, and that, therefore, removal would be more easily effected. Bone after bone, and occasionally a piece of soft tissue, were withdrawn, until, at the end of about an hour, the cavity was almost entirely emptied. I say almost entirely, because it seemed impossible to get every small bone away, and for several weeks afterwards an occasional bone would be thrown off *per vaginam* The cavity was thoroughly washed out with the disinfecting solution, and an examination made to discover the seat and extent of the rupture.

The cavity of the uterus was large and rough, and in the right side of its body there was discovered an opening through which two fingers could be readily passed into a cavity beyond.

The recovery of the patient was slow; indeed, her life was despaired of for weeks, during which time she suffered from numerous pyæmic abscesses. One of these abscesses was post-ocular, and resulted in the loss of the eye. She finally left the hospital, restored to health.

Removal of a Mammary Tumor and of Enlarged Axillary Glands; Primary Union.—Dr. W. H. Parish exhibited the specimens and read the following history. The patient from whom the specimens presented were removed is a lady of very slight stature, sixty-two years of age, and the mother of several children. There is no history of cancer in her family.

About twenty-five years ago she noticed a hard lump in the axilla, about the size of a partridge egg, painless, though tender on pressure. It was first noticed during a period of lactation. Subsequently she was again confined and passed through the usual time of lactation with a slight increase only in the size of the axillary tumor. For about twelve years after the first appearance of the axillary tumor she never noticed a lump in the breast. About twelve years ago, however, she, for the first time, recognized the presence of a mammary mass, then about the size of a partridge egg. This was about the menopause; at that time she lost in flesh, though her general health remained good.

The mammary tumor increased in size very gradually; continued free from pain, except when something would press unduly against it. About twelve months ago she thought the tumor had begun to increase in size a little more rapidly, and occasionally gave a sensation of soreness. This change in the tumor was ascribed by the patient to carrying in her arms a grandchild.

At the time of the operation the tumor in the breast was about the size of a small lemon, very hard and somewhat nodular, and was at the upper and outer border of the gland. It was perfectly movable over the pectoral muscle, and presented a distinct elevation above the general skin surface. The skin was not entirely movable over the mass, but was not hardened or otherwise altered in character. There was no nodular involvement of the integument. The superficial veins were not enlarged. The nipple was not retracted; seemed entirely normal, and no fluid could be pressed out of it.

There were three enlarged axillary glands, the largest very hard and a little larger than a partridge egg. There was no enlargement of the glands above the clavicle. Owing to the long duration of the masses, their entire mobility, the freedom of the skin from nodular infiltration, the absence of retraction of the nipple and of oozing from it, and also owing to the evident atrophy of the mammary gland, I concluded not to remove the entire breast, but only the tumor, including those of the axilla, and to remove also the integument overlying the mammary tumor. This I effected by an elliptical incision, and then extending the incision to the axilla, removed three enlarged lymphatic glands. It was not necessary to ligate any vessel; the oozing, which was not great, was stopped entirely by the use of hot water. The incision was about seven inches long. The edges were approximated by deep silk sutures. A few strips of rubber adhesive plaster were applied, and all covered with a layer of salicylated absorbent cotton, and the chest surrounded with a flannel binder. This entire dressing was allowed to remain until the fourth day, when, on removal of the cotton, it was seen that primary union had been secured throughout the entire incision. There was neither hardness nor swelling to indicate inflammation. On the sixth day the sutures were removed, and on the tenth day the patient sat up. No medicine of any kind, not even an anodyne, was given during the entire treatment.

The long duration and small size, the normal appearance of the nipple, the freedom of the skin from pitting and nodular infiltration, and the mobility of the mammary tumor over both the pectoral muscle and on the mammary gland, have led me to hope that the growths are fibromata, but the enlargement of the axillary glands and their induration make me fear carcinoma.

Microscopical Examination by Dr. Henry Beates, Jr.—The specimen presented by Dr. Parish is of unusual pathological interest. When it is remembered that the growth was present for nearly thirty years without undergoing a noticeable change, and only during the last year occasioned suffering and was accompanied with axillary involvement, the question of malignancy suggests itself, especially as the clinical history almost forces the diagnosis of adenoma. As many representative pathologists incline to the belief that typical mammary adenomata do not undergo carcinomatous degeneration, and many assume a conservative or noncommittal position; this instance is of unusual interest, and demands close study. Sections were made through the mass and including the cutaneous surface. The skin, so far as the stratum corneum and rete mucosum are concerned, is normal, but in the corium are areas of inflammatory changes. The radicles of several of the vascular papillæ are choked and surrounded by numerous embryonic cells and inflammatory corpuscles. The larger vessels are in a like manner involved, and the tissue in their immediate proximity infiltrated. The pars reticularis, where it becomes continuous with the subcutaneous connective tissue, is, in many places, the seat of proliferated connective-tissue corpuscles.

The *glandular structure* shows beautifully its purely adenoid character. The acini, although filled with cells and almost hidden from view, are, with care, easily distinguished. The interacinous connective tissue is hyperplastic. The hyaline membrana propria is partially destroyed and the acini filled with degenerated epithelial cells and cellular elements of increased size, possessing many nuclei. Some of the acini have the membrana propria entirely destroyed. The lymph spaces are occluded by cells, multinucleated and of increased size and irregular contour. The interacinous fibroid tissue presents incipient formation of stroma and aggregations of cells.

The axillary gland is completely altered in its structure, and instead of the mass of lymphoid cells occupying large spaces, bounded by the characteristic fibrous stroma with its triangular basal form, we have typical carcinomatous structure. Fibroid stromata joining at acute angles, forming numerous interspaces filled with irregular multinucleated cells, characterize the degenerated gland as carcinomatous. This fact, in conjunction with the changes seen in the mammary gland,

proves conclusively that the breast tumor was originally a typical adenoma, which, after thirty years, began to undergo malignant degeneration, and became a centre from which the axillary glands were infected.

DR. ROBERT P. HARRIS remarked that a point of great interest in the history of this tumor was the long period during which it remained dormant. He had had under observation a case in which a mammary tumor had remained perfectly dormant for seventeen years, during which two pregnancies occurred. After the second labor the tumor commenced to enlarge, and became painful; an operation for its removal was performed some months later, when it had attained the size of a duck's egg. A chain of nine enlarged glands was removed with the tumor. The tumor recurred in the same breast, and was followed by one in the other breast, and numerous hard nodular growths over the entire body. Her death was due to this cause.

Two aunts of this patient, living in the South, had died of cancer. A sister had a tumor in the abdominal wall, which was allowed to attain the size of a door-knob without interference. At that time Dr. Agnew and other surgeons were opposed to the advisability of an operation. After a year the tumor commenced spontaneously to discharge a purulent matter. It was then successfully removed by Dr. Agnew, who pronounced it an encephaloid growth. It had made no attachments to the underlying vital tissues, and has shown no signs of returning. Two years have elapsed since the operation.

NEW HAMPSHIRE MEDICAL SOCIETY.

Ninety-second Annual Meeting, held at Concord, June 20 and 21, 1882.

(Specially reported for THE MEDICAL NEWS.)

TUESDAY, JUNE 20TH. — The Society convened in Union Hall, at 11 o'clock A.M., with the PRESIDENT, DR. H. B. FOWLER, of Bristol, in the Chair, and was opened with prayer by Rev. Mr. Parkhurst, of Concord.

The roll of members showed one hundred and thirty present, and eighteen new members were admitted.

The usual committees for the session were appointed by the President, and the routine business of the programme occupied the time until 12 o'clock, when the PRESIDENT delivered

THE ANNUAL ADDRESS,

as is prescribed by the by-laws of the Association. He referred to the general prosperity of the Association, its harmonious working for the good of the profession, and referred to the necrology of the past year in fitting terms; afterwards he referred to the relations existing between the profession and the pharmacist, and condemned in unsparing terms the ethics of those who allow their names to be used in the public recommendation of elixirs, peptones, mineral waters, wines, etc., and withal with so much humor that his audience could not refrain from laughter from the ridiculous position in which such practices placed the profession.

The address was well received, and it was very evident that the country physicians, while holding fast to all pharmaceutical preparations that prove to be of actual worth, have but little sympathy with those who are ever ready to append their names to drugs, not officinal, and articles of doubtful utility, even though they hold a chair in some of our medical colleges or may be editors of some medical journal.

DR. CHARLES F. LESLIE, of Sunapee, read a

REPORT ON PRACTICAL MEDICINE,

devoting a large portion of the same to a consideration of *typhoid fever*, which has prevailed in his locality, giving some of his observations and conclusions.

He remarked that in the past eight years he had treated cases of typhoid fever in every month of the year, and among the old and young as well as the middle-aged.

The town of Sunapee is located on the shores of a lake of the same name, the water of which is very clear and cold, is 1200 feet above the level of the sea, and with very little alluvial deposit. The principal village of the town is situated at the outlet of the lake, and it has been observed by the Doctor that when the water in the lake was the highest the people in that vicinity suffered most from typhoid fever. It did not appear in his paper that the water of the lake was used for domestic purposes, therefore it would seem to be a coincidence rather than a cause of the disease.

DR. H. M. FIELD, Professor of Materia Medica at Dartmouth Medical College, read an essay on "*The Balsamic*," that was replete in character, and any mere abstract would fail to do the paper justice.

DR. E. F. MCQUESTIEN, of Nashua, read the *Report on Surgery*, giving a review of the legal case of Holt *v.* McQuestien, tried in Hillsborough County, in 1881, for alleged malpractice, in which the verdict was given for the defendant, and several other surgical cases where the ankle-joint was injured. He recommended that the Society prepare a new law which will oblige those parties bringing suits for malpractice to give bonds to indemnify the defendants if their charges are not sustained.

DR. G. L. MASON, of Laconia, delivered an oration on the *Now and Then* of the medical and surgical methods of the orthodox practitioners. He spoke of some of the remarkable cures effected by the heroic treatment of old, and then in a very happy manner contrasted the therapeutics of disease to-day with that of fifty years ago.

DR. M. T. STONE, of Troy, read a dissertation on *Tobacco*.

DR. H. M. FELT, of Hillsborough, submitted an essay on *Emetic Medication*, which was read by its title and referred to the Committee of Publication.

DR. D. P. GOODHUE, of Springfield, reported the death during the last year of Dr. A. B. Hoyt, of Grafton; Dr. E. K. Webster, of Pittsfield; Dr. Harrison Eaton, of Merrimack; Dr. John A. Dana, of Ashland; and appropriate obituaries were read and referred.

DR. SMITH, of Hanover, exhibited a "*horse-shoe*" *kidney*, and read an essay upon the subject.

DR. I. A. WATSON, Secretary of the State Board of Health, read a paper on

STATE MEDICINE,

recommending to the medical profession the educating of the people upon sanitary and hygienic matters as the only effectual method of the prevention of diseases that are produced by bad sanitary conditions. He pointed out many of the dangers of improper ventilation of dwelling houses, school-rooms, churches, public halls, etc.; also the serious results that follow water contamination, and the great danger of pollution of wells and springs from the filthy conditions that surround many houses. Many instances and illustrations were given, showing that the poison of typhoid fever and some other diseases might be conveyed a long distance in water currents even under ground and then produce disease in some other localities. He asserted, with proof, that the popular idea that ice was always pure because the process of freezing eliminated its organic impurities, was a false theory, and that ice from any source but that of pure water was dangerous to health. He believed that the public entertained false ideas concerning contagious diseases; that scarlet fever and diphtheria should always be as promptly and efficiently isolated as small-pox, since they were

infinitely more fatal diseases. The paper appealed strongly to the profession to endeavor to correct many erroneous ideas, and to leave no efforts undone to prevent disease and to secure the greatest possible good for the people.

WEDNESDAY, JUNE 21ST. — The Society met at 8 o'clock A.M., and reports of district societies, delegates, and other routine business was in order until 9 o'clock, when, by a by-law of the Association, the election of officers takes place.

The following were elected

OFFICERS FOR THE ENSUING YEAR:

President.—A. H. Crosby, M.D., of Concord.
Vice-President.—J. W. Parsons, M.D., of Portsmouth.
Treasurer.—D. S. Adams, M.D., of Manchester.
Secretary.—G. P. Conn, M.D., of Concord.
Anniversary Chairman.—A. P. Richardson, M.D., of Walpole.
Executive Committee.—Drs. J. W. Parsons, of Portsmouth; P. A. Stuckpole, of Dover; and M. W. Russel, of Concord.

The *Treasurer's Report* was read and accepted. It showed the finances of the Society to be in good condition. The Treasurer was directed to notify all who were in arrears, and to prepare a list of the members for publication in the Transactions for this year.

Several cases were reported. The Society then adjourned to meet in Concord, the third Tuesday in June, 1883.

CORRESPONDENCE.

POISONOUS EFFECTS OF SALIVA.

To the Editor of THE MEDICAL NEWS.

SIR: In a report of the proceedings of the West Philadelphia Medical Society, published in THE MEDICAL NEWS of May 27 (p. 585), I find the following remarks by Dr. Formad:

"Dr. Sternberg, of the U. S. Army, made recently some experiments, by injecting saliva under the skin of dogs, in the pathological laboratory of the University of Pennsylvania, and concluded that the poisonous effects were produced only by the saliva of persons who did not smoke, or who lived in hot climates. 'But,' said Dr. Formad, 'I am an inveterate smoker, and my saliva killed as promptly as any one's.' A student of mine, Mr. Claxton, made a number of experiments, and could not corroborate some of Dr. Sternberg's conclusions. On the contrary, he found that any saliva, even that of animals, promptly killed those experimented upon."

I am very sorry that my friend, Dr. Formad, has made it necessary for me to correct this very inaccurate statement of my experiments and deductions from the same.

I did not experiment on dogs in the pathological laboratory of the University of Pennsylvania, nor did I conclude that poisonous effects were produced only by the saliva of persons who did not smoke or who lived in hot climates.

During the progress of my experiments, *which were made upon rabbits*, I considered the possibility that the use of tobacco might neutralize the virulence of saliva, and consequently made notes as to whether or not those persons who furnished saliva for these experiments used tobacco. The result showed that this habit was without influence, and no mention is made of tobacco in my published report (*National Board of Health Bulletin*, April 30, 1881). If Dr. Formad had taken the pains to read this report, he would have found the following:

"The saliva of four students, residents of Baltimore (in March), gave negative results; eleven rabbits injected with the saliva of six individuals in Philadelphia (in January), gave eight deaths and three negative results; but in the fatal cases, a less degree of virulence was shown in six cases by a more prolonged period between the date of injection and the date of death. This was three days in one, four days in four, and seven days in one.

"*Query.* Is there any recognizable peculiarity in the saliva which exhibits the greatest degree of virulence?

"*Answer.* In the case of Dr. Sternberg, whose saliva shows an exceptional virulence, the teeth are sound, the secretions of the mouth normal in physical properties and reaction, and the general health good. There is, perhaps, an unusual flow of saliva, but no other noticeable peculiarity.

"*Query.* Is there any plausible hypothesis by which this difference in virulence can be explained?

"*Answer.* This question will require for its solution more extended experiments. In the meantime it may be mentioned, as having a possible bearing upon the subject, that Dr. Sternberg has been engaged to a considerable extent, during the past two years, in studies which have brought him in contact with septic material. Dr. Formad, of Philadelphia, whose saliva killed (after a longer interval) two rabbits, is pathologist to a large hospital, and consequently is constantly brought in contact with septic material. Mr. N. and Mr. B., whose saliva killed all the rabbits operated upon, (four), are residents of seaport towns in Cuba.[1]"

Finally, Dr. Formad says that Mr. Claxton, a student of his, made a number of experiments, and could not corroborate some of Dr. Sternberg's conclusions. "*On the contrary, he found that any saliva, even that of animals, promptly killed those experimented upon.*"

How the additional fact that saliva of animals kills rabbits, when injected beneath their skin, is opposed to the facts reported by me with reference to the lethal effects of hypodermic injections of *my* saliva, I fail to see. I do not refer in my report to the effect produced by the subcutaneous injection of saliva, other than that of man, not having made the experiment. But I have experimental evidence that "*any saliva*," that is to say, all saliva, does not kill rabbits, for, as stated in the above quotation from my report, I had three negative results in Philadelphia and four in Baltimore with human saliva other than my own. I have, also, recently introduced the sputa of several tubercular patients beneath the skin of rabbits without producing fatal septicæmia. Whether these rabbits will become tuberculous, remains to be seen, and will be duly reported when the experiments are completed.

Yours respectfully,
GEO. W. STERNBERG,
Surgeon U.S.A.

FORT POINT SAN JOSE, SAN FRANCISCO,
June 8, 1882.

MEDICAL TESTIMONY FOR THE DEFENCE IN THE MALLEY CASE.

To the Editor of THE MEDICAL NEWS.

DEAR SIR: In your editorial criticism of my testimony in the "Malley case," in your issue of June 24th, you have done me injustice, unintentionally, I have no doubt, as you must have derived your information from the notes of the testimony in the newspapers. Most of these notes were inaccurate in many particulars.

[1] The possibility that this septic condition of the secretions of the mouth may bear some relation to the protection which these Cubans and myself enjoy against yellow fever, which is a disease presenting many points of resemblance to septicæmia, has occured to me, and without, at present, laying any great stress upon this possibility, I think it worthy of further experimental consideration.

In the first place I made no comments "on the conduct of the chemical investigation."

Second. You have mistaken the place where the examination of the hymen was made, for that at which the post mortem was held by Dr. Prudden; the first being held in a low, dark basement used as a prison in West Haven; the second at the shop of the undertaker in New Haven. I did "disapprove of the dark-room, or morgue, where the autopsy of the hymen was made."

Third. I did not *admit on cross-examination* the absence of inflammation of the stomach in cases of arsenical poisoning, but stated the fact with the authorities on my direct examination.

Fourth. My attention, while on the witness stand, was not called by either the prosecution or defence to the subject of arsenic eating. If it had been, I should have said that the Styrians become gradually accustomed to its use, and consequently do not suffer from its toxic effects.

Fifth. I did not *maintain the "constancy of inflammation of the stomach as a result of arsenic in toxic doses;"* but stated that inflammation of the stomach was sometimes absent, and gave the reasons for it, with the authorities.

Very truly yours,

P. A. Jewett.

New Haven, June 29, 1882.

NEWS ITEMS.

BROOKLYN.

(*From our Special Correspondent.*)

The St. John's Hospital.—The new structure of this hospital was formally opened June 24th by Bishop Littlejohn, assisted by numerous clergy of the Protestant Episcopal Church. The building just completed is a five-story brick and stone chapel and westerly wing, 139 feet in length and 95 feet broad. The cost was $80,000 exclusive of land. It will accommodate 125 beds, open to all irrespective of creed, sex, or age.

The New Code.—At a recent meeting of the Medical Society of King's County, the question of endorsing or rejecting the new Code of the State Medical Society was brought up. No vote was taken on its merits, but its consideration was ordered to be made a part of the regular order of business of the regular meeting in October next.

LONDON,

(*From our Special Correspondent.*)

Davy's Rectal Artery-Compressor.—I am not aware whether Mr. Richard Davy's rectal compressor, or lever, has found any favor with American surgeons, but it has been used now on many occasions in England, and, on the whole, with signal success. Having just witnessed a fatal accident with it, however, I feel compelled to give a note of warning concerning its use. Lest some of your readers may not be familiar with the lever, let me just say that it is a well-turned straight circular wooden rod, about the circumference of the little finger, and two feet in length. It is used by passing about seven inches of it (in an adult) up the rectum and towards the side to be operated upon; on then raising the handle or part outside the anus, the upper end compresses the common iliac artery just in the depression between the bone of the sacrum and ilio-pectineal line. Amputation at the hip-joint, or high up in the thigh, can then be performed without any arterial hemorrhage, and the vessels are controlled with remarkable ease. I have seen the lever used on several occasions, and there can be no doubt that it answers admirably, and that, when properly applied to the artery, there need be no anxiety on the score of hemorrhage.

In Mr. Davy's little *brochure* (surgical lectures) details of several cases in which it has been used will be found. The lever has lately been modified, having been made smaller than it was originally, and it has been provided with a gum-elastic sheath—this is flexible, and is easily passed into the rectum and takes the direction of the gut, and the rigid rod is then passed into the sheath. As the case to which I am about to refer has not been made public, I will not mention any names; but, as I assisted at the operation, I can vouch for the accuracy of the facts. The patient was a man of middle age, on whom an operation for ununited fracture high up in the shaft of the femur had been performed, without success, and amputation of the limb was determined on. Mr. Davy was requested to use his lever. This he did, first of all passing up an injection of olive oil, then the flexible sheath, and lastly the wooden lever. There was no difficulty experienced in all this, but it was found necessary to raise the handle of the lever more than is usually the case before all pulsation in the femoral artery ceased. The vessel was completely controlled; absolutely no arterial blood was lost; and at the close of the operation we all congratulated ourselves on the success of the lever. The patient progressed favorably for twenty-four hours. Symptoms of peritonitis then made their appearance, and the man rapidly sank and died. At the autopsy the usual signs of peritonitis were found, and the cause was detected in a perforation of the rectum just seven inches from the anus. The rectum elsewhere appeared healthy; there was no sign of ulceration about the perforation, and there can be no reasonable doubt but that it was produced by the end of the lever. I should say it was the right common iliac artery that was compressed. It is commonly stated that the same thing has occurred in the practice of an eminent surgeon in one of our large northern towns, but the case has not yet been published. But whether or no, it has now happened in the hands of him who originated and has closely studied this method, and is more experienced than any one else in its employment. Mr. Davy had no suspicion at the time of the operation that anything had gone wrong. The only other mishap with the lever that I am aware of is the impossibility of passing it sufficiently high up the rectum. This once happened to myself. After an oil injection, and using all the force I considered safe, I quite failed to pass the lever more than four inches. After the death of the patient, we found a sharp bend of the rectum, which rendered it impossible to pass the lever, even on the post-mortem table. Although I have been a warm supporter of the lever hitherto, I now feel that its use must be abandoned. It is now demonstrated that at any rate for compressing the *right* common iliac artery it is *dangerous to life*, and considering that there are other means of controlling the vessels, which in skilful hands are not unsuccessful, I shall never again use the lever. Whether it may be safely used in all cases for compression of the *left* artery, is another question as to which I should not like to dogmatize.

Medical Advertising in the Lay Press is the ethical discussion most heard just now. A short time ago nearly one whole side of the *Times* was occupied with advertisements of medical works published by Smith, Elder & Co. The matter has been taken up by the *Lancet* and by the College of Physicians, and it is hoped that this flagrant breach of professional conduct may lead to such an expression of opinion as will check the practice altogether. We have no wish to see medical works puffed by the same artifices which are used to sell cheap sherries, mineral waters, and whiskey.

VIENNA.

(*From our Special Correspondent.*)

DEATH OF PROF. CARL MAYSHOFER.—Carl Mayshofer, Professor of Gynecology, in the Vienna University, died upon June 3, in his forty-sixth year, at Franzensbad. He was born June 2, 1837, in the city of Steyer, his father being a physician. He completed his gymnasial studies in Kremsmünster, where he studied zealously the natural sciences, especially astronomy. After completing his medical studies in Vienna, he became an operative pupil of Schuh, afterwards Arlt's assistant. During this time, he wrote a noteworthy treatise upon ophthalmology. Later, he determined to devote himself exclusively to obstetrics and gynecology. As the assistant in the first obstetrical and gynecological klinik in the Allgemeines Krankenhaus (Carl Braun's wards), he published a paper which attracted very general attention. He sought to investigate the etiology of the puerperal process, and to demonstrate the parasitic nature of childbed fever in this brochure. Such a publication, twenty years ago, is sufficient to establish the high intellectual character of the man. Among his numerous more recent literary ventures may be named the following: "Ueber die Anwendung des Secale Coruntum in der Geburtshülfe," "Ueber die Entstehung des Geschlechtes beim Menschen," "Gegen die Hypothese, die menschlichen Eierstöcke enthielten männliche und weibliche Eier," "Eine Bemerkung zu J. C. Dalton's Ansicht vom Corpus luteum der Schwangeren," "Die Ueberwanderung der Eier," and finally an article in Pitha-Billroth's text book, "Ueber Sterilität, Entwicklungsfehler und Entzündungen des Uterus." Notwithstanding all this, notwithstanding his high general culture, he was not successful in obtaining the position for which he most earnestly strove. Several years ago, he went to Russia to obtain the recognition denied him at home. In Liflis and St. Petersburg, though acknowledged as a most skilful gynecologist, his life was rendered so unpleasant by professional jealousies, that he returned to Vienna to devote himself almost exclusively to literary work. Franzensbad became his final home, a short time since, when a severe disease of the liver ended his useful, fruitful, and brilliant life.

PROF. DUCHEK'S CHAIR OF INTERNAL MEDICINE.—There still exists great difficulty in the selection of a successor to Duchek. Prof. Nothnagel, of Jena, was warmly supported at the last meeting of the College of Professors. The Department of Education and the College of Professors are not adverse for once, in a great number of years, to a foreigner.

PRIVAT DOCENT DR. HANS CHIARI'S APPOINTMENT AS EXTRAORDINARY PROFESSOR OF PATHOLOGICAL ANATOMY IN THE UNIVERSITY OF PRAGUE.—Dr. Hans Chiari very unexpectedly has been appointed Extraordinary Professor of Pathological Anatomy in Prague, and Prof. Eppinger to the same chair in the University of Graz. This change in the expected order of events has created the liveliest curiosity in South German medical circles.

BILLROTH'S "RUDOLFINERHAUS."—One of Prof. Billroth's pet schemes for the education of female nurses has been carried into execution by the opening of the so-called "Rudolfinerhaus" upon the 31st of May. A number of soldiers, wounded in the existing insurrections in Bosnia and Montenegro, fill the wards. Baroness V. Villo-Secca, acts as Superintendent, Prof. Billroth, the founder of the Institution, as Director, and Dr. Gersuny as Chief Surgeon.

CELEBRATION IN HONOR OF BILLROTH'S DECLINATION OF LANGENBECK'S CHAIR IN BERLIN.—The students, privat docents, and friends of Prof. Billroth are preparing for a grand ovation to be tendered him in honor of his recent refusal to leave Vienna in order to occupy Langenbeck's vacant chair in the University of Berlin. A torchlight procession composed of medical students, accompanied by Strauss's orchestra, will conduct Prof. Billroth to the reception hall, when ceremonies befitting the occasion, will be observed.

THE NEW YORK COUNTY MEDICAL SOCIETIES AND THE NEW YORK CODE.—Delaware and Chemung Counties are the latest New York County medical societies to repudiate the new Code. The Tompkins County Medical Society is the only County society which has formally adopted it, and it stands alone in this action. Twenty-three of the sixty County societies of the State have so far condemned the new Code.

HEALTH IN MICHIGAN.—Reports to the State Board of Health for the week ending June 24, 1882, indicate that cholera infantum and cholera morbus have greatly increased; that erysipelas, inflammation of the bowels, and intermittent fever have increased; and that scarlet fever, influenza, and pneumonia have decreased in area of prevalence.

Small-pox was reported present during the week ending June 24, and since at six places, as follows: At Detroit and Flint, at Battle Creek (one new case), in Polkton, Ottawa County (one new case), in White Cloud, Newaygo County (four cases in mild form, all having been vaccinated this spring), June 22; at Grand Rapids (three new cases June 28, thirty cases in all, including convalescents; one death June 28).

HEALTH IN PROVIDENCE, R. I.—DR. E. M. SNOW, Superintendent of Health, reports 169 deaths in Providence during the month of May, or 3 less than in the preceding month, and 26 less than in May, 1881. Of the total number, 44 deaths were of children under five years of age. Zymotic diseases caused 21 deaths, which is equal to 12.42 per cent. of the total mortality. This percentage indicates a favorable condition of the City's health. There were 29 deaths from consumption, which heads the list in point of numbers. Then follow in order: pneumonia, 19 deaths; diseases of the heart, 14; old age, 9; convulsions, 8; bronchitis, enteritis, typhoid fever, and whooping-cough, each 6; apoplexy and inflammation of the brain, each 4 deaths. There were 3 deaths from scarlet fever, and 1 each from measles and diphtheria. Small-pox caused no deaths. It is pointed out that not a single death was caused by accidents, which is an extremely rare circumstance. The mortality from pneumonia in this and the two preceding spring seasons has been above the average, and has been accounted for by the cold, damp weather in these years.

HARVARD MEDICAL SCHOOL.—Dr. David W. Cheever has been elected to the chair of the Professorship of Surgery, vacated by the resignation of Dr. Bigelow. At the Commencement held June 28th, Dr. Bigelow was elected Emeritus Professor of Surgery and received the degree of LL.D. from the University.

THE CENTRAL ALUMNI COMMITTEE OF THE UNIVERSITY OF PENNSYLVANIA, which has been formed to cooperate and advise with the trustees in the future management of the institution, was formally organized on June 28th, and will at once take an active interest in University affairs. The committee elected the Rev. James W. Robbins, D.D., its Chairman. The members drew lots for their terms of office. The representatives of the medical department will serve as follows: Drs. John H. Packard and Traill Green *for one year*,

C. H. Mastin and Wm. H. Van Buren *for two years*, S. Ashhurst and I. Minis Hays *for three years*, A. H. Smith and W. H. Klapp *for four years*, Caspar Wister and John F. Meigs *for five years*.

OPHTHALMOSCOPIC MIRROR, WITH DOUBLE FOCUS.—In order to overcome the inconvenience of using an ophthalmoscope with a mirror of a single focus for the examination of the direct and inverted image, Dr. Galezowski has devised an ophthalmoscope which has a small mirror of 8 centimetres focus inserted in the centre of the large mirror of 25 centimetres focus.—*Le Progrès Méd.*, June 3, 1882.

WHITE LEAD MANUFACTURE.—Attention has been called to the considerable increase in the number of persons engaged in the white lead manufactories at the East-end of London who became victims to plumbism in its various forms. Agitation on this subject is by no means a new phenomenon. It has frequently been ventilated in these columns; indeed, so deeply did we feel the importance of it that in 1874 our Sanitary Commissioners reported on it specially. But though attention has persistently been drawn to the matter, little has been done towards the prevention of the evil. After each agitation the manufacturers and inspectors of these lead works remain for a time on the alert, and the necessary precautions are adopted to protect the workpeople; but in course of time this vigilance is relaxed, and cases of lead-poisoning become more and more numerous till public indignation is again aroused. The process of white lead manufacture is divided into six stages: the making the lead plates, the exposure of these plates to the fumes of acetic acid, the removing the deposited carbonate of lead from the plates, levigating and grinding it, drying it, and finally packing it. The most dangerous parts of the work are the picking off and handling the crusts from the lead plates, and the packing. In the latter process the dry and brittle white lead is removed from the drying-room in baskets carried on the heads of the operatives to the packing-room, where it is broken up and placed in barrels ready for export. The dust arising from the highly dried white lead speedily covers the clothes, hands, and face, and, unless respirators are worn, is inhaled. Women and young girls are mostly engaged in this part of the business, and this is the reason why females suffer apparently more than males from the effects of lead. The same holds good with regard to the removal of the white lead from the plates, this also being performed by females. The least dangerous part of the business—the levigating and grinding whilst wet, and the drying, which is not dangerous if respirators are used—is performed by men. Although instances of extreme susceptibility to the influence of lead have come under our observation, and cases have occurred where severe lead colic has developed a few days after work had been undertaken for the first time in a white lead manufactory, still there is no doubt that if the regular precautions were strictly enforced, together with the suggestions made by our Commissioners relative to the wearing of strong leather gloves by those who are obliged actually to handle the white lead, and the necessity of wearing respirators during the packing process, the cases of plumbism occurring in the course of the year from these causes would cease to be a matter for consideration. But to attain such a result, constant supervision must be exercised over the operatives. It is not enough for the manufacturer to provide, and the inspector of factories to approve of, the general regulations and appliances, if they are not obeyed or used. An overseer ought to be appointed to each factory, whose sole duty it should be to keep a vigilant eye constantly on the operatives, and insist on the precautionary measures being carried out to their fullest extent. Neglect or disobedience should be punished by fine or dismissal; and in order to ensure the requisite degree of vigilance on the part of the overseer, his wages in great measure should depend on the immunity attained during the year. Lastly, in all cases where it can be proved that the ordinary precautions have not been rigorously enforced, and cases of plumbism have in consequence been of frequent occurrence, the manufacturer should be proceeded against, and if the case were proved, heavily fined. It is only just that those who by carelessness or greed have brought about such a mishap should be made to suffer in some shape and degree, whilst it is but fair to the ratepayers, on whom the responsibility of ultimately maintaining the broken-down victims of plumbism falls, that the chief offenders should also feel the burden.—*Lancet*, May 6, 1882.

THOUGHT-READING.—A meeting, at which Dr. Crichton Browne presided, and which was attended by a number of scientific and literary men, was held at the Marlborough Rooms on the evening of Saturday last, the 6th instant, to witness an exhibition of the phenomena of "thought-reading" by Mr. Stuart Cumberland. That gentleman, with great promptitude and precision, went through the usual performance of finding articles that had been hidden during his absence from the room, of spelling out words thought of by the subjects of his experiments, and of disclosing the date of birth of several members of his audience. At the close of his demonstrations, Monsignor Capel, Professor Ray Lankester, Dr. Hack Tuke, Dr. Simpson, and others, complimented him on the success which had attended them, and expressed their conviction that his power in "thought-reading" was superior to that of any professor of the art who had as yet appeared in London. Professor Croom Robertson said that, having been a member of a small committee which investigated the pretensions of Mr. Bishop as a thought-reader about twelve months ago, he could testify confidently that Mr. Stuart Cumberland was correct in his interpretations or readings in a larger proportion of instances than Mr. Bishop; and that there was this great difference between Mr. Bishop and Mr. Cumberland, that, while the former always left it to be understood that he was aided in his experiments by an occult force or mysterious influence which he could not himself comprehend, the latter acknowledged that he was aided in all his revelations simply by naturally quick and highly trained perceptive faculties, and that he was guided entirely in his explorations and discoveries by movements in the hands which he held or pressed to his forehead. Monsignor Capel said that "thought-reading" or "willing" is practised in hundreds of drawing-rooms in London; and the chairman expressed his belief that Mr. Cumberland is engaged in a salutary work exposing the impositions of charlatans, and the superstitions of weak-minded enthusiasts. Some spiritualists who were present did not seem inclined to accept Mr. Cumberland's account of his own extraordinary powers, but were evidently disposed to regard him as a clairvoyant, in spite of his disclaimers, and of his plain-spoken denunciations of spiritualism in all its manifestations.—*Brit. Med. Journal*, May 13, 1882.

THE MEDICAL NEWS *will be pleased to receive early intelligence of local events of general medical interest, or which it is desirable to bring to the notice of the profession.*

Local papers containing reports or news items should be marked.

Letters, whether written for publication or private information, must be authenticated by the names and addresses of their writers—of course not necessarily for publication.

All communications relating to the editorial department of the NEWS *should be addressed to No. 1004 Walnut Street, Philadelphia.*

ORIGINAL LECTURES.

CLINICAL REMARKS ON SCARLET FEVER.

Delivered in the New York Foundling Asylum, April 22, 1882,

BY PROF. J. LEWIS SMITH, M.D.

GENTLEMEN: We call your attention to-day to one of the most important diseases of childhood, viz., scarlet fever. The following history of a case which you have seen, and which has proved fatal, has been prepared for us by the resident physicians, Drs. Kortright and Swift.

Annie K., aged two and a half years, was well, with the exception of an eczema of the scalp, until the night of April 3, when she was attacked with vomiting and diarrhœa. She was feverish and drowsy, and at 2 P. M. on the 4th, the scarlatinous efflorescence appeared upon her neck, body, and lower extremities; tongue coated; pharynx red; temperature (axillary), 103°; pulse, 160. The symptoms and aspect indicated a grave form of the malady, and the usual sustaining treatment was ordered. On April 5 the temperature was 102°; pulse, 144; tongue less coated; eruption fading; less stupor; no albumen in urine. April 6, morning temperature, 102°; pulse, 160; passed a restless night; stools thin and too frequent; has grayish patches in the throat; P. M. temperature, 103⅕°; pulse, 150. April 7, the diarrhœa continues; she has copious muco-purulent discharge from the nose; P. M. temperature, 103⅗°; pulse, 160. April 10, the temperature has continued at about 103°; the patient is very sick, with a constant foul-smelling discharge from the nostrils; breath very offensive; temperature, 103½°; pulse about 180. April 12, general appearance a little better, but the posterior surface of the fauces is completely covered by a thick pseudo-membrane; had four loose stools last night; temperature and pulse the same as at last record; a dark and offensive exudation over the fauces, and a dark, foul discharge from the nostrils; examination of the chest negative. April 14, much prostrated; temperature, 104¼°; pulse rapid and weak; respiration noisy; diminished resonance over lower two-thirds of left side of chest; ulcers upon the mouth and tongue; fauces red and ulcerated. April 17, pulse, 150; temperature, 100½°; general appearance somewhat better; the diarrhœa still persists; diphtheritic patches have appeared upon the lips; moist râles in left side of chest. The symptoms continued nearly the same until April 23, when she died. A dull percussion sound and distinct bronchial respiration were observed in the left scapular region during the last days of her life.

The post-mortem examination has been made by our curator, Dr. W. P. Northrup, who will now show you the specimens.

Autopsy.—April 22, nine hours after death: body well nourished; the tissues have a jaundiced hue; lips sore; on turning the head to one side pus runs from the left ear, and dirty muco-pus from the mouth. Brain normal; the petrous portion of the left temporal bone has been opened, and the middle ear found full of pus which communicated freely with the external ear through a perforated membrana tympani; the Eustachian tube can not be traced in the sloughy tissue, but there is apparently a passage filled with pus from the ear to the fauces; opposite the greater cornua of the hyoid bone are two deep ulcers, each having about the diameter of a ten-cent piece, and with sloughy and offensive base and sides; the left ulcer communicates by a ragged and wide sinus with a dark and sloughy cavity of about four drachms capacity; this cavity is located in the neck, under the angle of the jaw, apparently occupying the site of a disintegrated gland.

Larynx and *Trachea.*—The surface of the larynx has a dusky dirty appearance, sprinkled with little cheesy-looking spots and covered by a dirty foul-appearing liquid as if some of the ichorous pus had escaped into it from the neck; about one and a half inches below the vocal chords there is an unmistakable pseudo-membrane; below this, near the bifurcation, the trachea has a bright red color, as if a pseudo-membrane had been peeled from it, leaving the surface raw. The detachment of a pseudo-membrane from this part, if it did occur, must have been ante-mortem, for the organ has been carefully handled in making the autopsy.

Lungs.—Between the apex of the left lung and the median line, the tissues of the neck dissected upward, are found indurated, yellow, and giving an offensive odor, showing that the cervical cellulitis had extended downward further than usual. The bronchial glands have undergone hyperplasia, being enlarged and hard. The right lung is normal; about one-half of the left lower lobe is consolidated, and when cut is found to be gangrenous and offensive.

Abdominal Organs.—The liver appears somewhat enlarged; the spleen, which is apt to be enlarged and softened in severe infectious diseases seems normal; the surface of the stomach has a congested appearance, and is covered with mucus; mesenteric glands enlarged, pale, and firm; Peyer's patches swollen and pale; at lower end of ileum some pigmentation of these glands; in the large intestine the solitary glands are enlarged and a few of them pigmented, otherwise no marked change in this part of the intestine; kidneys pale; cortex thickened, and markings indistinct.

Microscopic Examination.—In the pia mater, perhaps a little increase of cells; meninges of brain otherwise normal. The trachea shows well-marked diphtheritic inflammation; it contains a film of pseudo-membrane; evidences of inflammation occur also upon the laryngeal surface, though less marked than in the trachea. The solidified portion of the lung exhibits the ordinary lesions of broncho-pneumonia with some interstitial change. In the kidneys we find parenchymatous nephritis, with some cell growth in the Malpighian bodies.

Gentlemen: Before considering the points of interest in this case, I wish to call attention to certain facts relating to scarlet fever in general, with some of which you may be familiar, but others may be new to you.

The evidence is strong that this disease does not originate *de novo*, for countries have been free from it for centuries, till it was imported by commerce. It was introduced into North America by Europeans about the year 1735, into Iceland in 1827, into Greenland in 1847, and recently into Australia. That it has appeared in certain localities without any known exposure, is attributable to the fact that the poison is so subtle and transmissible that it is conveyed to long distances in packages, books, and even in small articles of merchandise or reading matter.

Etiology.—The theory that the acute and indeed the chronic infectious diseases are caused by micro-organisms, or, as they are now designated, microbes, of a vegetable nature, commonly discarded at first, and

considered chimerical, is rapidly gaining ground in the profession. This theory is so important and is attracting so much attention that it will be well to consider the facts in reference to it so far as they apply to scarlet fever.

Unfortunately, as a bar to the successful study by experimentation of the relation of micro-organisms to the infectious maladies which afflict the human race, some of them do not occur in animals, or they occur in a changed and mitigated form, as typhoid fever, the miasmatic fevers, syphilis, and the eruptive fevers. Others, however, can be produced in their typical form in animals, as diphtheria, and others still occur chiefly in animals, and originate in them as chicken cholera and splenic fever or anthrax of the herbivori, known to the French as charbon, and transmissible with all its malignancy to man.

That minute organisms occur in the blood and tissues in infectious diseases, and in immense numbers when the type is severe or malignant, has long been known and admitted, but then the belief held by many, and which seemed very plausible, was that they did not sustain a causative relation to the diseases in which they occurred, but were the result of those diseases; that they quickly sprang into existence in consequence of the vitiated state of the system produced by disease, just as fungi appear on decaying organic substances, or, as an example in the human system, as the oidium albicans quickly appears in certain diseased conditions of the buccal surface and its secretions. Now an important step has been taken in the way of determining whether the microbes are a cause or the result of the infectious diseases which promises to lead to brilliant and decisive discoveries. It has been found possible to cultivate the microbes contained in the blood, tissues, and secretions of certain of the infectious maladies, and, after a series of cultivations, so that these organisms are far removed from the animal substances which contained them, and with which they were so intimately associated in the individual, they have been employed for inoculation, with the important result that the primary disease was reproduced.

These experiments have been made, and the original diseases reproduced after a series of cultivations with the microbe of splenic fever, with that of chicken cholera, that of murrain, recently with that of tuberculosis by Koch, of Berlin, and with the microbes of certain other maladies, so that it now seems as if the general principle will soon be established that minute vegetable organisms are the contagia of the various infectious maladies, of scarlatina as well as of the others.

Perhaps the scarlatinous microbe has already been discovered. In the *London Medical Gazette*, for January 28, 1882, is an account of its supposed discovery by Dr. Ecklund, of Stockholm, a microscopist and parasitologist of repute. He says that scarlet fever is rarely absent from the Swedish capital, and from the barracks and other dwellings on the Isle of Skeppsholm. In the urine of scarlatinous patients he has constantly found a prodigious number of discoid corpuscles, oval or round, their diameter being less than $\frac{1}{1000}$ millimetre, or from $\frac{1}{800}$ to $\frac{1}{10}$ that of the red blood-cell. They are colorless or yellowish-white, surrounded by a distinct cell-wall, and containing a well-defined nucleus of a deeper hue; sometimes one or more nucleoli may be seen. Dr. Ecklund positively asserts that he has found these same organisms in vast numbers in the soil and ground water of the Isle of Skeppsholm, in the mud of the trenches, and in the greenish mould upon the walls of the old barracks, where scarlet fever was most rife. Furthermore, he states that scarlet fever has occurred in children after drinking milk mixed with the ground water of the island, and he observed a case which followed immersion in one of the trenches of the island, and drying the clothes in a small room. In one instance, scarlet fever broke out immediately in a block on exposure of the ground water by excavations.

It is evident that the discovery of a microbe under such circumstances does not prove that it is the cause of the disease. This can only be determined by inoculation or by experiments which furnish the conditions of scientific exactness, and we must wait for further light on this interesting subject.

Whatever the specific principle of scarlet fever is, whether a micro-organism or a chemical substance, its effects are well understood from clinical observations. Without doubt it enters the system by the breath, and infects the blood. That it resides in the blood has been ascertained by inoculation with this liquid, which reproduces scarlet fever in its typical form. From the blood it enters the tissues and secretions. Hence handkerchiefs or linen containing the saliva or mucus of a patient, the epidermic scales shed abundantly in the desquamative period, and probably also the urinary and fecal evacuations contain the poison, so that they are highly infectious. Even the discharge of a scarlatinous otorrhœa is believed to be contagious for a considerable period after the primary disease has abated.

Scarlatina is not only communicated by direct exposure to the patient, but also by exposure to objects which happen to be in his room during his illness, and to which the poison becomes attached, such as books and toys.

In England observations have been made which show that scarlatina has been communicated by infected milk. The disease occurred in the family of a milkman, and the milk, before it was distributed, remained for a time in a kitchen which had been occupied by the patients. The milk was taken by twelve families, and in six of these the disease occurred almost simultaneously. At this time cases were so few that scarlatina was not considered an epidemic, and there was no exposure to the carrier, nor to members of the affected family (Taylor). In another instance, a woman and her son had scarlet fever while they were serving milk to several families, and the disease appeared in all these families except one which consisted of old people (Bell). It is known that milk absorbs volatile substances so as to be flavored by them, as is shown in the experiment of placing it in an open vessel in a box with a pine-apple, and it may in a similar manner become infected by the specific principle of scarlet fever, or it may be infected by detached particles of epidermis, which is not improbable, when one convalescing from scarlet fever is allowed to milk the cows or prepare the milk for distribution.

The scarlatinous virus surpasses that of any other eruptive fever, except small-pox, in its tenacious attachment to objects and its portability to distant localities. Hence the literature of this disease contains the records of many cases in which the poison was conveyed long distances, retaining its virulence to the full extent, and causing an outbreak of the malady in the localities to which it was carried. In New York City so frequently has scarlet fever, as well as diphtheria and measles, been contracted in the public schools from the clothing or persons of well children or from books that come from infected houses, that the Health Board now exclude from the schools all children who come from such houses, even though they live on separate floors from those occupied by the patients. In one instance that came under my notice, a washerwoman, whose child had scarlet fever, communicated the disease to an infant in the household where she was employed, by placing her shawl over the cradle in which it was lying. A physician of my acquaintance went from a scarlet fever patient to a family several

streets distant, and took one of their children upon his lap. After the usual incubative period, this child sickened with a fatal form of the malady, and the remaining children of the household were in time affected. In New York scarlet fever has seemed to me to be not infrequently communicated through school-books, which, profusely illustrated by pictures, and rendered attractive to the young, are often allowed to lie upon the bed of the scarlatinous patient, and be handled by him during convalescence, or even during the course of the disease if it be mild.

The young librarian of a circulating library of a sunday-school, the pupils of which came largely from the tenement houses, was occupied a considerable part of a day in covering and arranging the books. After about the usual incubative period of scarlet fever, he sickened with the disease. His two sisters were immediately removed to a rural township, three hundred miles away, and to an isolated house where no scarlatinous case had ever occurred. About one month after his recovery, and after his room had been fumigated by burning sulphur, and the bed clothes and linen had been thoroughly washed, and all articles suspected to hold the poison had been either destroyed or disinfected, the brother visited his sisters in the country. Three weeks subsequently to his arrival, one of these sisters sickened with scarlet fever, and a week later the other also. It seems that the exposure must have occurred several days after his arrival in the country, from some book or other infected article in his possession. About two months elapsed after the last case, the family had returned to the city, the infected room in the country house had been thoroughly fumigated by burning sulphur for a good part of a day; when a little girl from an inland city remained a few days in this house, and probably often entered the room where the young ladies had been sick. In a few days she also sickened with a fatal form of scarlatina. Such histories and experiences are not unfrequent; they are common during epidemics of scarlet fever. They indicate an extraordinary attachment of the scarlatinous poison to objects, and show that it is not gaseous nor readily volatilized.

(*To be continued.*)

ORIGINAL ARTICLES.

THE FUNCTION OF THE INTESTINAL JUICE.

BY CHARLES L. DANA, A.M., M.D.,

PROFESSOR OF PHYSIOLOGY IN THE WOMAN'S MEDICAL COLLEGE, OF NEW YORK; PHYSICIAN TO CLASS OF NERVOUS DISEASES, NORTHEASTERN DISPENSARY; MEMBER OF AMERICAN NEUROLOGICAL ASSOCIATION.

A SERIES of experiments has been made by me to test the digestive power of the intestinal juice.

The evidence regarding the properties of this secretion has been quite conflicting. This will best be seen by the accompanying table compiled in part by Dr. G. M. Garland,[1] and completed by myself.

My experiments were performed in the following manner: The animals were etherized; a loop of the jejunum was pulled out and ligatured in two places, from one to two feet apart. An opening was made near each ligature, and the intestine between was thoroughly washed out with pure water. Either white of egg, or fat, or starch, was then inserted, and the incisions sewed up, or else two more ligatures were used so as to exclude the openings. The abdominal wall was then sewed up, and the animals given a small dose of morphia. In four to six hours they were killed, and the contents of the isolated loops examined.

I can think of no *positive* elements of error in this method, provided it be carefully carried out. Of course, the operation is likely to affect the secretion by lessening or checking it. Consequently, if no results were obtained, it would not show that the intestinal juice is inactive. But positive results would be of value.

Experiment No. 1.—Eight-pound dog, full-grown; ligatured and washed out eighteen inches of upper part of jejunum. Dog had been fasting twenty-four hours. Injected ʒiij raw egg-albumen beaten up for most part into a foam. Dog nearly died under the operation. Gave ♏x Magendies' solution of morphia; dog recovered, but slept; killed four hours later. Two drachms of albumen only could be recovered; ligatures were tight; tested contents for peptone; no reaction.

This experiment showed nothing, except that under the above method peptone is not formed by putrefaction, nor by action of pepsin said to be found in parenchymatous juices and in nearly all tissues. As to this point, Schiff and Quincke state that glycerin-extracts of intestinal mucous membrane do not digest albumen.

Experiment No. 2.—Twenty-pound dog; full-grown; fasting; operated as above. Injected ℥ss coagulated egg-albumen finely mashed in a mortar; dog recovered well and walked around. Magendies' solution, ♏iij were given; intestine opened five and a half hours later; very little secretion on the surface; considerable water had been injected with the albumen, and most of this was absorbed. Ligatures tight; could collect only ʒss to ʒj of albumen. Everything was carefully washed off and tested for peptone, with caustic potash and cupric sulphate, first boiling and filtering to remove albumen. The purplish-violet color, showing peptone, was present. It is possible that some of the albumen was lost, but certainly a considerable part was absorbed either as peptone or "precipitable products."

Experiment No. 3.—Twelve-pound dog; fasting; opened intestine as before. Injected in one loop, twelve inches long, ℥ss olei dulcis; in another loop, three feet below, ℥ss coagulated white of egg mashed. Dog recovered well; received a small amount of morphia. Five hours later opened intestine; reaction acid. In the loop where the *oil had been* placed, recovered ʒiij. Ligatures seemed tight, but some oil might have been lost in the injection. At any rate I could see no chyle in the lacteals, either with the naked eye or the microscope. The acid reaction may have been due to the development of fatty acids.

From the loop where *albumen had been placed*, I recovered about ʒij. This, on being tested as above, showed a strong *peptone reaction.*

Experiment No. 4.—Fifty-pound dog; operated as before. Twenty-five centimetres (ʒvj) of olei dulcis inserted in a loop of jejunum one foot long; dog recovered well. Six hours later, killed, and

[1] Physiological Laboratory, Harvard Medical College, Boston. Collected papers, 1873–1877, p. 11, Intestinal Digestion.

loop examined. Nearly all the oil was recovered; reaction of intestinal wall acid; no emulsion seen; lacteals not injected; examination of villi under microscope showed that no fat whatever had been taken up by the epithelium.

Experiment No. 5.—Condemned horse; chloroformed. Opened small intestine thirty feet from ileo-cæcal valve; ligatured one and a half feet; washed out, and inserted ℥vj melted lard. Reaction of intestine was alkaline; intestine was nearly empty; horse had not been fed for six hours. Also ligatured three feet of intestine, eight feet nearer stomach; reaction here was alkaline; washed and inserted ℥xij hydrated starch; animal recovered well. Was given morphia q. s.; six hours later killed. *Recovered* ℥v–℥ij *of lard*, as near as could be estimated, but some might have been lost. Lacteals could not be seen to be injected either with naked eye or microscope; no emulsion seen; reactions neutral.

From the loop where starch had been placed only ℥xj could be recovered. Tested for glucose; it gave a very decided reaction. Quantitative analysis showed that there was a little less than one drachm of glucose in the eleven ounces.

The results of the above experiments are summarized in the table. They indicate that the intestinal juice digests albuminous matter, and turns hydrated starch into sugar. This view agrees with the results of the majority of recent experimenters. The evidence regarding the action of the juice on fats is negative, but most experiments show that it has no action, and mine, if anything, confirm that view.

ACTION OF INTESTINAL JUICE ON

	ALBUMINOIDS.	STARCH.	FATS.	CANE SUGAR.	GRAPE SUGAR.
BUSCH. Intestinal fistula in a woman, high up.	Protein bodies are dissolved with the appearance of putrescence and the odor of ammonia.	Acts more energetically upon starch than upon protein bodies.	Unaffected; not absorbed unless mixed with bile.	Unaffected.	
THIRY. Artificial fistula.	Fibrin is crumbled in the normal secretion; this does not occur if the juice be neutralized or acidified. Coagulated white of egg and red muscle are unaffected.	Starch is not converted into sugar.	Unaffected.	No change after hours of digestion.	Intestinal juice has no fermentative influence.
LEUBE.	Fibrin is crumbled; other albuminoids are unchanged.	Unaffected.		Cane sugar is changed to grape sugar.	Lactic and butyric fermentation occurs as the result of presence of vibriones.
QUINCKE. By glycerine extract.	Fibrin is dissolved occasionally; raw or cooked flesh and coagulated white of egg are unaffected.	Starch is changed to sugar after a long time.	Unaffected.		Converts sugar into lactic acid after a long time (12 to 24 hours).
SCHIFF. By glycerine extract.	Albumen, fresh casein, cooked or fresh muscle are dissolved in the secretion of the duodenum.	Action on starch almost as energetic as that of pancreatic juice.	Oils are emulsified.		
WITTICH.	Fibrin is not digested.	Energetic diastatic action in one instance.			
PASCHUTIN.	Fibrin and other albuminoids are unaffected by water infusions. Action of normal secretion is especially doubtful on fibrin.	Starch is converted into sugar.	Fats are imperfectly emulsified.	Cane sugar is changed into grape sugar by a ferment found only in the small intestines.	Acid fermentation occurs after a few hours.
BERNARD.	Fibrin is the only albuminoid substance attacked.	Acts very feebly on starch.		Chief function of secretion of small intestine is to digest cane sugar; secretion of large intestine is impotent.	
GARLAND. Thiry's method.	Fibrin is crumbled and converted into peptones, whether the secretion be alkaline or acid. Digestion of coagulated white of egg is doubtful. Fibrin is digested by a 0.2 per cent. HCl solution.	Starch is changed into sugar.			
MASLOFF.[1] By Thiry's method, and by infusion of mucous membrane of dogs and pigs.	*Raw* fibrin in *acid* fluid was dissolved. Raw and cooked meat and coagulated albumen were not affected.	Starch changed to sugar in alkaline fluid reaction; less rapidly in neutral or acid fluid.			
EWALD.[2] Fistula in man.	Turned albumens to peptones.	Starch to sugar.	Fats emulsified.		
COLIN. Thiry's method in a horse.		Starch to sugar.	Fats emulsified.		
DEMANT.[3] Intestinal fistula low down, in man.	No action.	Starch to grape sugar.	Fats with fatty acids emulsified; neutral fats not affected.	Cane sugar to grape sugar.	
BROWN and HERON.[4] By extracts of the mucous membrane, and other methods.	Not tried.	Starch to grape sugar, slightly.	Not tried.		Maltose to grape sugar actively.
DANA. Isolating intestine in dogs and horse.	Albumen turned to peptone.	Starch to grape sugar.	?

[3] Demant, B., Ueber die Wirkungen des menschlichen Darmsafts. Virchow's Archiv, lxxv. 3, p. 490.
[4] Brown, H. T., and Heron, J., Am. Chem. Pharm., 204, 228. Proc. Royal Soc. London, 30, 393. They say: The pancreatic diastase turns starch into dextrin twenty per cent., and maltose eighty per cent. The intestinal juice turns these latter into glucose.

We may be asked to explain, if the intestinal juice is inert, how it is that when the pancreatic duct is tied, or when the pancreas is diseased, there is not always a fatty diarrhœa, or much fat in the feces. Bernard, Langendorff,[1] Cash,[2] and others, have shown what medical observation confirms, that such fatty stools do not always occur.

To this it may be said, that in warm alkaline fluids neutral fats may develop *acids and become emulsified.* And Cash[2] has also shown that the gastric juice helps, or can help, develop fatty acids. The same observer asserts that fats may be taken up before emulsification, and that this process takes place, or can take place, within the villi. At any rate, we can understand the possibility of a limited absorption of fat without assuming a specific action of the intestinal juice.

In conclusion, then, it seems very well established that the intestinal juice in some animals supplements the action of pepsin and trypsin on proteids, and turns hydrated starch to sugar. Its *rôle* is probably not a large one as regards digestion, but it may in some way assist absorption; for the intestine in flesh-eaters is pre-eminently an absorptive organ.[3]

Intestinal dyspepsia is, I believe, almost always due either to the stomach's throwing insufficiently digested food into the intestines, or to atony of the muscular walls and defective absorption. The trouble as regards the intestine is, in my opinion, more with muscle and absorption, than with secretion. The stomach may be at the bottom of the disturbance all the time, unloading itself with indecent haste, or with its work half done.

A CONTRIBUTION TO CEREBRAL LOCALIZATION.

BY H. J. BERKLEY, M.D.,
OF BALTIMORE.

THE subject of the present paper was Mr. J. H., of Baltimore, æt. seventy-three, who for many years had suffered from cardiac trouble, both mitral and aortic. It was only about a week before his death that he first came under my care; I found him extremely ill from the defective circulation, and at any moment likely to die.

On looking into the face of the patient, I noticed a peculiar twitching of the left angle of the mouth, localized as far as I could perceive in the zygomatic muscles. No other portion of the face participated in the mono-spasm, and with the exception of a slightly blank look on this side (of the face), there was nothing worthy of remark.

I now inquired of his friends how and when this twitching had commenced, and learnt that it had begun suddenly some thirty months previous, and was unaccompanied, at that time, by either unconsciousness or pain; and that it had since continued regularly, neither increasing nor diminishing from the period of its commencement.

Many years before he had become blind in the right eye, but the vision of the left was nearly normal, and there was no ptosis on either side.

The tongue was put forth perfectly straight, neither deviating to right or left, the movements of the organ were free, and unaccompanied by any incoördinated motion, and his voice was clear and distinct.

There was absolutely no paralysis of any of the extremities, neither inferior nor superior, and up to a short time before his death he was accustomed, daily, to take considerable exercise.

His mental condition was what one would expect to find in an old man in his dotage, unaccompanied, as far as I am able to learn, by any special peculiarity. Death occurred suddenly.

Autopsy twenty-four hours after death.—The thoracic viscera were first examined. The heart and great vessels were greatly diseased. The aortic valves were covered with calcareous plates, and were insufficient; the auriculo-ventricular orifice of the left side was completely surrounded by a bony ring; the mitral valves were thickened, opaque, and, like the aortic, covered with plates of calcareous formation and insufficient. The aorta for some distance beyond the valves was strewn with atheromatous patches. The right side of the heart did not participate in the disease.

The brain: The skull was well formed, the bones of moderate thickness, and were not adherent to the membranes. The dura mater was everywhere of natural appearance. The pia mater was thin, transparent, easily detached from the cortex, was nowhere adherent to the convolutions, not even over the spot of degeneration, and showed no signs of pre-existing inflammation.

The cerebral arteries, anterior and posterior, were strewn with atheromatous patches, even in the smallest arteries visible to the eye, they could easily be seen; but no embolism or rupture could be found, though carefully looked for.

The pia mater was now removed, and the cortex examined. The convolutions were very intricate, well formed; the two hemispheres were quite asymmetrical; in fact, the previous history of the patient showed that he had been a man of very considerable intellectual powers, especially possessing a considerable amount of elocutionary talent. The sulci penetrated deeply between the convolutions.

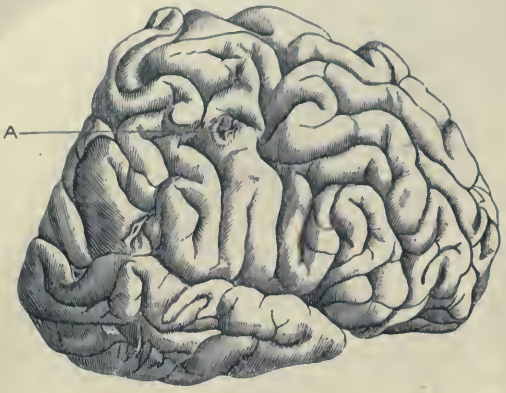
On the ascending frontal convolution of the right side, one and a half inches above the margin of the Sylvian fissure, in a location corresponding to the seventh centre of Ferrier, a nodule of calcareous degeneration was found of nearly circular shape, three-sixteenths of an inch from side to side, and of a corresponding diameter from above downwards.

The depth was very slight, certainly not greater than the one-half of the thickness of the cortical gray matter. It looked as if many months before there had been an occlusion, probably from an embolism, of one of the smaller surface arteries of the gray matter, which had since undergone calcareous degeneration, a result which not unfrequently occurs in like lesions. The left hemisphere, the cerebellum, the cord, medulla, and pons were healthy.

[1] Langendorff, O. Archiv f. Anat. and Phys., 1879, pp.
[2] Cash, M. Archiv für Anat. and Phys., 1880, p. 323.
[3] For discussion of this, see I. Munk's Phys. des Menschen u. der Säugethiere, p. 169.

The case seems to me to be one of the greatest interest in localization of the centres of the face; first, because the foyer is of minimum size, and absolutely unaccompanied by other lesions; and, secondly, because of the few known uncomplicated lesions of this portion of the motor zone of the brain.

Neither Ferrier, Charcot, nor De Boyer describe in their works an unmixed lesion of this portion of the motor zone, and, as far as I am able to discover, it is unique.



A, the lesion.

Ferrier remarks (Localization oi Cerebral Diseases), that "the cases on record in which paralysis limited to the face, unaccompanied by aphasia, or paralysis of the hand or arm, has been found in connection with cortical disease, have been due to lesions of the right hemisphere; but in none can the lesion be said to be circumscribed." The three following examples, cited by Ferrier and De Boyer, resemble more nearly the present case than any others.

A case reported by Gowers (Path. Transactions, 1876). It was "a case of left hemiplegia, which gradually recovered, with the exception of a very marked paralysis of the inferior facial muscles. The lesion was a hemorrhagic extravasation in and beneath the upper half of the præ-central sulcus, which had pressed upon the convolutions bounding it, viz., the posterior extremity of the middle and superior frontal, and corresponding part of the ascending frontal of the right hemisphere."

The case related by Hitzig "was of a French soldier, who, two months after a bullet-wound on the right side of the head, began to be affected with clonic spasms in the left side of the face. These were followed by transient but complete paralysis of the left side of the face and left side of the tongue. Clonic spasms occurred also in the left hand.

"After death an abscess was found corresponding to the seat of the injury, situated in the ascending frontal convolution, between the præ-central fissure and the fissure of Rolando.

"It should, however, be noted that there were indications of meningeal inflammation over the whole surface of the right hemisphere, though there was no cerebral softening except in the neighborhood of the abscess."

The third case is related by Hervey (*Bull. Soc. Anat.*, 1874). "This was a case of right facial paralysis with aphasia. A focus of softening was found anterior to the fissure of Rolando, at the junction of the third frontal with the ascending frontal convolution of the left hemisphere."

All are complicated, however, by more or less surrounding inflammation, and in the one that corresponds best with our present case, that of Gowers, the paralysis was caused by pressure upon, not disease in, the ascending frontal convolution.

The exceedingly small extent of the degeneration calls attention to the fact that it was an irritative, not a destructive, lesion, and also that the amount of space involved could not possibly cover the entire surface which supplied motor impulses to the muscles that participated in the spasm, otherwise we would have had paralysis, not mono-spasm, of the zygomatici.

In concluding, I must again repeat and recall attention to the main point, viz., that the diseased portion of the cortex was entirely unaccompanied by any other focus of degeneration, either on or within the cerebral hemispheres.

MEDICAL PROGRESS.

RESECTION OF THE STOMACH.—A. W. C. BERNS (*Nederlandsch Tijdschr. voor Geneesk*, 1881, S. A.) reports the case of a woman aged 49 years, who had suffered since 1878 with symptoms of chronic gastric catarrh, in whom the objective signs of cancer were first detected in the beginning of 1881. When Berns first saw the patient in April of this year, the entire abdominal cavity as far as the navel was occupied by the tumor and dilated stomach, and as the symptoms of obstruction of the pylorus were increasing in severity, it was resolved to attempt the excision of the tumor. The operation was rendered very difficult by the extensive adhesions formed; the vena cava was exposed for a length of ten centimetres, and a large portion of the pancreas had to be removed. After the removal of two cancerous nodules in the lesser omentum, the pylorus was excised, a wound of twenty centimetres long (two-thirds the length of the lesser curvature) being necessary on account of the existence of isolated cancerous nodules. Billroth's method of uniting the stomach and duodenum was made use of. One hundred sutures and more than two hundred and fifty ligatures were used. The patient lived four hours and a half after the operation, death probably occurring from shock, as the autopsy showed that the stitches and ligatures were all in position, and no blood or intestinal contents had escaped into the peritoneal cavity.—*Centralb. f. d. Med. Wissen.*, May 27, 1882.

TREATMENT OF PLEURITIC EFFUSIONS BY RESPIRATORY GYMNASTICS.—DR. DESCAMPS has studied the action of respiratory gymnastics on pleuritic effusions (*Revue de Thérap.*, April 1, 1882). The conclusions of his paper, read to the Society of Medicine at Antwerp, were as follows: 1. There is, in the treatment of affections of the chest in general, and of pleuritic effusions in particular, an important factor of which but little note has been taken up to the present time, notwithstanding the facility of employing it. This factor is the act of respiration. 2. Deep and regular respiration may be opposed to the impediment to the circulation—to the congestion of the lung, in many cases in which external or internal influences tend to produce it. It may prevent or impede the attack of illness. 3.

When the air inspired is pure and wholesome, a very favorable effect is exercised in declared pulmonary affections by regulating the gaseous and nutritive changes, by maintaining the permeability of the bronchi, by favoring circulation, and removing congestion of the pulmonary tissue, without speaking of the general good effects which are produced by the more complete formation of the blood. 4. In cases of pleurisy with effusion and compression of the lung, the act of respiration, if well regulated, may act in a very favorable manner, or the absorption of the exudation, and on the unfolding and progressive return of the lung to its normal size, by opposing its atrophy. For this purpose, in producing the converse of the tendency which exists in these cases, the breathing should be carried on by the sound lung as little as possible, so as to force that which is compressed to respire and to become dilated as much as possible. This result may be attained by an habitually full and deep respiration, the body being in such a position, whether standing, sitting, or lying, that the filling of the chest may be reduced to a minimum on the healthy side and raised to a maximum on the affected side. In pleurisy, the respiratory action should be put into practice at a suitable time, and should not exclude the preliminary or concomitant use of other means which may be indicated. 5. In cases of thoracentesis, the best method of avoiding the accidents which accompany and sometimes follow this operation is to favor the unfolding and the expansion of the lung by regulated respiratory exercises before, during, and after the operation. 6. The same exercises, both preparatory and consecutive, are very useful in cases of empyema, whether spontaneous or produced by operation. The pulmonary circulation, rendered more easy and more active by more regular and complete respiration, exercises a favorable influence on the general circulation, and may thus contribute to the clearing and to the return to the normal condition of important organs which have either become hyperæmic or inflamed, such as the brain, the liver, the kidneys, the peritoneum, through the liver, and the intestines themselves.—*London Med. Record*, May 15, 1882.

The Removal of Nasal Polypi.—Dr. Morell Mackenzie discusses the various operative methods of removing nasal polypi and states that the mode of treatment he generally adopts is to remove the polypi with his punch-forceps and then to apply the electric cautery to the base of the growths. This method will generally succeed in effecting a rapid cure, but when recurrence repeatedly takes place, if the growth springs from one of the turbinated bones, he removes the portion of the bone from which the polypus originates by means of a special instrument which he has devised for the purpose. It consists of fine hollow forceps having toothed edges on one side and smooth edges on the other, whilst between the two a sharp cutting blade can be rammed down. The portion of the turbinated bone required to be removed is seized by the forceps, the smooth blade being on the outer side. The knife is then pushed home and the portion of the bone easily removed. He wishes it to be understood, however, that though he considers the removal of a portion of one of the turbinated bones perfectly harmless, he regards it as an operation rarely required.—*Arch. of Laryngology*, April, 1882.

Epidemic Cerebro-spinal Meningitis.—The seventeen cases which Jaffé relates (*Deutsches Arch. f. klin. Med.*, Bd. xxx., H. 3 and 4, 1882), and which were mostly observed by himself, are not recorded for the purpose of setting up new theories concerning cerebro-spinal meningitis, but are intended to correct many errors which exist in regard to etiology, etc. He, therefore, first gives a summary of cases of like nature and of the results of all observations. The author maintains that the meningitic virus is a specific one, and considers it a waste of time to endeavor to prove its connection with other infectious diseases. It is certain that the disease in question is a specific infectious one, which may occur sporadically as well as epidemically, and may be spread by contagious as well as by miasmatic influence. As we are not yet clear as to the nature of the virus, we must, for the present, consider the two questions, as to the origin of the virus and the etiology of the disease, as unanswered; but, as a fact, we can record that it exists, and, as probable, we may assume that it is less a miasma than a contagium. Whether it be fixed or volatile, whether "vivum" or otherwise, or if parasitic, we know not as yet. Jaffé has examined, microscopically, the blood and exudations found in the cerebro-spinal cavities, but has found no organisms of any kind. He feels himself justified, therefore, in denying that cerebro-spinal meningitis is a parasitic disease (from a modern point of view).

Prodromal symptoms were found in ten cases. Headache occurred in fourteen, vomiting in fourteen, and delirium in ten cases; of the latter, two were of a maniacal character, and had been admitted as suffering from delirium tremens. Episthotonos occurred sixteen times; hyperæsthesia, eight; anæsthesia, once only; ocular changes, ten times; aural troubles, once, in the form of purulent otitis media, with perforation of the membrana tympani. In two pneumonia, in one bronchitis, and in one gangrene of the lungs occurred. There were two cases of ulcerative endocarditis, complicated once with purulent pericarditis. Splenic swelling was observed thrice, passive albuminuria once, arthritic affections five times.

The duration was two or three days as the minimum, four months as the maximum. Ten cases ended in death, seven in recovery; the mortality being 59 per cent. The diagnosis is most difficult in the early days of the sporadic cases. We have to distinguish between the diseases idiopathic (traumatic) spinal or cerebro-spinal meningitis, tubercular meningitis, typhoid fever, intermittent fever, asthenic pneumonia, tetanus, delirium tremens, and acute mania. The etiology of the first disease is an important aid, but it must be borne in mind that wounded persons are most sensitive to the meningitic virus; it is often impossible to distinguish tubercular meningitis, as two of the reported cases show. Typhoid fever is recognized by the gastric symptoms, which soon appear, and the absence of spinal symptoms, as well as the presence of the splenic tumor; intermittent fever by the beneficial effect of quinine. The other diseases are distinguishable in their further progress.

The treatment consisted in the application of ice to the spine and administration of narcotics, calomel in large doses, lukewarm and cold baths. The author found abstraction of blood, prolonged baths, and the administration of antipyretics to be useless, the latter disturbing the digestive faculties and lowering the patients.—*London Med. Record*, May 15, 1882.

Extirpation of a Cystic Tumor in a Bleeder.—C. Thiersch, in the *Arch. f. klin. Chir.*, xxvii. p. 265, reports a case in which he undertook the extirpation of a cystic tumor situated over the zygoma of a patient with marked hemorrhagic diathesis, hoping to be able to restrain the bleeding by moderate pressure under Lister's dressing until the vessels had closed. In spite of the ligation during the operation of twelve small arteries and the closure of the wound with eight catgut sutures, a few hours afterwards, when the pressure had to be reduced on account of the pain it was causing,

numerous extravasations formed on the forehead, cheeks, eyelids, upper lip, and gums, and when the dressing was removed on the third day, the wound was found to be distended with blood, so destroying any hope of primary union. This bleeding continued up to the entire closure of the wound, and on the eighth day an artery spurted as if freshly cut. On the thirty-ninth day the patient was discharged cured, having from the eighteenth to the twenty-third day suffered from an attack of facial erysipelas, while for weeks the extravasations continued, causing a mottled appearance of the entire face and neck. The difficulty in the healing of wounds in bleeders, is, as this case shows, not only in defective formation of new vessels, but also, even under the Lister dressing, of preventing bleeding by pressure, and consequently rendering healing by first intention possible.—*Centralb. f. d. Med. Wissen.*, May 27, 1882.

THE SOURCE OF BOTHRIOCEPHALUS LATUS.—Many investigators have occupied themselves with the problem of the source of bothriocephalus latus. Knoch, twenty years ago, believed that he had solved it, and that the ovum or embryo taken into the intestinal canal of a dog developed there into a perfect tapeworm, without passing through an intermediate stage in any other habitat. But this conclusion was not confirmed by others, and, in the opinion of Leuckart, Kuchenmeister, and others, is certainly erroneous. Other statements on the subject amount merely to more or less probable suspicions founded on what has been ascertained of the origin of other tapeworms. Our knowledge of the subject has, however, been materially advanced by an investigation by Dr. Braun, of Dorpat, a locality where the worm is compartively frequent. He has published an account of his researches in a recent number of Virchow's *Archiv*. He started with the assumption, justified by all known facts regarding the history of other tapeworms, that, like them, the bothriocephalus must have an intermediate stage, and therefore presumably a change of host. Recorded facts show that all animals in the intestines of which bothriocephalus has been found, are fish eaters, either entirely or partially, and, further, that an organism has been detected in fishes which has been regarded as the early form of bothriocephalus. An investigation of various fish brought to the market at Dorpat showed that some had, encapsuled in the intestine, the early asexual forms of bothriocephalus. This, however, was not sufficient, since the intestines of fishes are not eaten by man, and the presence of the organisms in them would not account for the occasional endemic prevalence of the disease. Braun therefore examined the parts of the fish which are eaten, especially the muscles, the sexual glands, and the liver, and he found in the pike (*Esox lucius*) numerous young bothriocephali not only in the above parts, but also in the spleen and other viscera. They were found in almost every pike brought to the market. Hence, an infection of man can readily occur, and in that district the pike is common, and is extensively eaten by the lower classes. The scolices were also found abundantly in the eel, which is also a favorite article of food. It remained to be proved, however, that the muscle scolex of the pike or eel was capable of giving rise to the adult form. A number of experiments were therefore undertaken with the cat and dog, which were fed with the infected muscle. In no case were either ova or segments of bothriocephalus found in the feces before the special diet was commenced, only the ordinary tæniæ of these animals. When, however, the organisms from the pike were added to a strict diet, including, as the only drink, distilled water, segments of bothriocephalus were found in the fæces, and in one case, in the cat, the sexually ripe form of bothriocephalus was obtained, corresponding perfectly with that of man. The practical consequences of this conclusion are sufficiently obvious.—*Lancet*, June 3, 1882.

COMMUNICATION OF THE LUNG WITH THE AORTA.—DR. BOHAY presented to the Medical Society of Buda-Pesth, the specimens obtained from a case of phthisis pulmonalis, in which a cavity in the apex of the left lung communicated by an opening four millimetres in diameter with the left side of the arch of the aorta, which was as thin as paper and drawn over to the left side by adhesions to the lung. The aneurism was not diagnosticated during life. Such cases are extremely rare, Rokitansky having only seen one similar one.—*Journ. de Méd. de Paris*, June 3, 1882.

PILOCARPINE IN DIPHTHERIA.—We described, a few months ago, the results obtained by a number of Continental observers on the treatment of diphtheria by the method recommended in such eulogistic terms by Guttman: the administration of pilocarpine with the view of effecting the detachment of the false membranes by the secretions produced. Those results were to some extent contradictory, although the balance of opinion was strongly against the method, as rarely useful and often fraught with no small amount of danger in many cases. This conclusion is strongly confirmed by the subsequent experience of several physicians who have used pilocarpine. The results they have obtained have been lately summarized by Dr. Picot in the *Revue Médicale de la Suisse Romande*. Demme, for instance, in nineteen cases thus treated, failed to observe in most of them any arrest of the spread of the false membranes, and in nearly half the cases tracheotomy had to be perfomed. In two or three cases of moderate degree of severity pilocarpine seemed to be of some service, but its use was not exempt from difficulty, especially on account of the various tolerance exhibited by children, so that doses which in some produced alarming collapse were well borne by others. Of three cases reported by Payrandeau, two were children, and both died in a state of collapse. No favorable result was obtained by Faludi, of Pesth, and an extensive trial of the method by Archambault more than confirms the doubtful opinion which he previously had expressed. He treated eighteen cases by this method, and only three recovered, although eight of the cases are said to have been of a benign form. No larger proportion recovered, however, of those which were treated by other methods, but the detailed observation of his cases has led Archambault to the conclusion that the effect of pilocarpine is positively injurious. The abundant diaphoresis exposes the patient to risk of catarrh, and the abundant mucous secretion produced, in itself involves a danger to respiration. Schmid, Laschkewitz, and Charkow, have met with only unfavorable results. Of ten cases treated in this way by the latter, all died. The experience of several other physicians—Saint-Denis, Lewin, Warschauer, Dentan, Maunier, and Ferrière—has been scarcely less unfavorable, although not equalling the disastrous experience of Bernier de Bournonville, who failed to save a single one of seventeen patients thus treated. A very small minority of those who have written on the subject consider the treatment of positive utility. Most of these seem to have drawn their conclusions from mild cases, and it may be noted that one of them —Duchini—lost four out of five cases thus treated. Almost all agree that the influence of the drug is confined to the detachment of the false membranes; that it has no influence on the poison itself is shown by the fact that it is powerless to prevent relapses.—*Lancet*, June 3, 1882.

TREATMENT OF PHTHISIS BY INHALATION.—DR. STRETCH DOWSE read a paper on this subject before the Northern District Branch of the British Medical Association. He prefaced his paper by referring to the recent very valuable discovery of Dr. Koch, concerning the tubercle-bacillus; and he thought that the inflammatory theory of tubercle, and Dr. Sanderson's recent lectures at the College of Physicians on Inflammation, tended to support rather than to detract from the results of Dr. Koch's original investigations. Dr. Dowse, through the kindness of Dr. Blake, was enabled to show to the members present many forms of respirators, including one of Dr. Blake's invention, which were useful and adapted for the purposes of inhalation. Dr. Dowse said that it was more than ten years ago when he first began to treat pulmonary consumption by inhalation; and he regreted that, until recently, he had not carried out his experiments with that care which so important a subject demanded. During the months of September, October, November, and December, 1881, he had treated his patients, in the North London Hospital, for consumption, by several forms of inhalation; and he almost invariably had good results. He thought, however, that the process of inhalation was far from perfect, and he hoped for better results in the future. Short histories and notes of several cases were brought forward, as evidence in favor of this mode of treatment. He spoke particularly of the value of acetic ether as an inhalant; in fact, he went so far as to say this drug was, in his opinion, capable of disolving nascent tubercle. The mixture which he generally used had the following composition: ℞. Thymol. ʒiij; ætheris acetici ʒiij; ætheris sulph. ʒi; creasoti ʒiij; acidi carbolici ♏xv; terebinth. ad ʒiv. Ten drops to be used at a time for an inhalation. He laid great stress upon continuous inhalation: for instance, two hours morning, afternoon, and evening, as well as during the whole night.—*Brit. Med. Journ.*, May 27, 1882.

DISTINCTION BETWEEN CADAVERIC AND PLANT ALKALOIDS.—H. BECKURTS (*Arch. der Pharm.*, Feb. 1882) has made a number of experiments as to the relations between these alkaloids. Since the knowledge of the fact that in dead bodies, through the influence of putrefaction, alkalodial bodies—septicines, or the ptomaines of Selmi, may be formed, which, in their chemical reactions, show a behavior quite analogous to that of the plant bases, the attempt has been repeatedly made to discover characteristic points of distinction between them.

General reactions, by means of which it may be readily and certainly decided whether a plant alkaloid or one of so-called ptomaines is in question, have remained as yet unknown. The discovery of such must also remain for the present at least problematical, as long as the knowledge of the chemical nature of the ptomaines remains so deficient, and when under the latter designation an entire group of compounds is comprehended, the members of which, apparently, formed under the same conditions, exert a varying physiological action, and probably stand also in very loose chemical connection. Our interest, therefore, must be attracted the more to a recently published essay of Brouradel and Boutmy (*Comptes Rendus*, 1881, p. 92, 1056), wherein they maintain to have found in potassium ferricyanide a reagent which will distinguish these two classes of bodies. Plant alkaloids, according to the statements of these chemists, do not change this salt, whereas the ptomaines reduce the same at once to potassium ferrocyanide, which may be recognized by a precipitate of Prussian-blue on the addition of a ferric salt. An exception to the rule is morphia and veratria, of which the former has a strong reducing action, the latter to a lesser extent.

The importance of this statement for forensic chemistry induced the author to repeat the related experiments, but only with regard to the behavior of the plant alkaloids towards potassium ferricyanide, as the reducing action of the ptomaines has been emphasized by all investigators as a characteristic property, and therefore, does not require a repeated confirmation by experiments.

The experiments were so conducted that for each a centigramme of the alkaloid was dissolved in five cubic centimetres of water with the aid of dilute sulphuric acid, then two drops of a ten per cent. solution of potassium ferricyanide added, and subsequently one drop of a very dilute neutral ferric chloride solution.

Morphia and colchicine reduced the potassium ferricyanide very strongly; the mixture, upon the addition of ferric chloride, became immediately dark-blue. A less strong, but still plainly perceptible reduction, recognizable by the formation of a greenish-blue liquid after the addition of ferric chloride, and from which immediately, or after a short time, flocks of Prussian-blue were precipitated, was effected by aconitine (English and German), brucine, conine, digitaline, nicotine, strychnia, papaverine, narceine, codeine, and, in accordance with the statements of the named chemists, veratrine. To these may also be added picrotoxin (in natural solution), while atropia produced no reduction.

If it be accepted that the ptomaines which, according to a recent investigation of A. Casali (*Gazz. Chim.*, 1881, p. 314), are considered as amido acids, possess a stronger property of reduction than most alkaloids, it is seen from the communicated experiments that a distinguishing reaction between plant poisons and ptomaines with regard to their behavior towards potassium ferricyanide cannot be observed.

The author finally mentions that he is still occupied with the examination of the crystalline or amorphous precipitates which are produced by potassium ferricyanide and ferrocyanide with the alkaloids mentioned.—*Amer. Journal of Pharm.*, May, 1882.

TREATMENT OF TYPHOID FEVER WITH QUINIA AND SALICYLIC ACID.—At the meeting of the Société Médicale des Hôpitaux, held May 26, M. LEREBOULLET read, in the name of M. SOREL, a paper on this subject. This memoir, suggested by the researches of M. Hallopeau, is based upon an analysis of ninety-seven cases. Instead of first employing calomel, as advocated by M. Hallopeau, M. Sorel gives from 50 centigrammes to 1.8 gramme of sulphate of quinia in the morning, and from 2 to 4 grammes of salicylate of soda during the day, its use during the night being suspended if the antipyretic effects appears to have been sufficiently marked. The simultaneous use of these two drugs can be long continued with evil effects, without producing ringing in the ears, delirium, marked dyspnœa, epistaxis, or intestinal hemorrhage; abundant sweats and eruptions of sudamina are the most frequent effects, and can, without doubt, be attributed to the salicylate of soda. This treatment does not interfere with the simultaneous treatment of complications, should they arise, and tends to render the temperature curve horizontal, though it does not shorten the disease or prevent complications.—*Gaz. Hebdom.*, June 2, 1882.

TREATMENT OF HEMORRHOIDS BY FORCIBLE DILATATION OF THE ANUS.—Having referred to the dangers accompanying the usual methods of radical treatment of hemorrhoids, *i. e.*, excision, ligature, and cauterization, PROF. SUBBOTIN (*Mejdunarodnaia Clinica*, No. 1, 1882) advocates a fourth method, which is alleged to be entirely free from such dangers as subsequent pyæmia, stricture of the anus, secondary hemorrhage, general

peritonitis, etc. This operation is forcible dilatation of the anus and lower part of the rectum, recommended, about thirty years ago, by Maissonneuve, and, after many years of oblivion, in 1876-77, again introduced into practice by Verneuil and Fontan, and later by Guyon, Trélat, and other French surgeons. The author, from his own experience, draws attention to the simplicity, safety, rapidity of curative action, and efficiency of this method, which is described by him as follows. On the day before the operation, the bowels are thoroughly opened by a purgative; and, immediately before the dilatation, the rectum is washed out by an enema. The patient being brought under the influence of chloroform, and placed on his left side, with his thighs fully flexed, the operator stands behind the patient and introduces a bivalved Recamier's anal speculum. Then he gradually and cautiously opens the speculum (introduced down to its handle); and, when all the rugæ of the anorectal mucous membrane have been effaced by stretching, he leaves the instrument opened to its widest extent *in sitû* for two or three minutes, and then removes it. With this action the treatment comes to an end, no after-treatment being required. The operation lasts about six to eight minutes. The immediate effects of the dilatation consist: 1, in a paretic state of both rectal sphincters, which exists three or four days, and then is followed by normal contraction of the parts; and 2, in complete relaxation or disappearance of the hemorrhoid varices. Small piles usually disappear at once, never to return; large ones remain visible for some time after the operation as soft, lax, and empty capsules. These are gradually diminished, and, as a rule, finally disappear, or remain in the shape of simple polypi, causing no discomfort to the patient. According to the author, the action of dilatation in the treatment of hemorrhoids is twofold. First, by relaxing the sphincters, it removes the cause of stagnation of blood in the beginnings of the hemorrhoid veins; and, secondly, it expels the contents of the varices and compresses their walls in such a way as to cause their adhesion and obliteration of the cavity. Prof. Subbotin points out only two contra-indications to forcible dilatation. They are, suppuration and incipient gangrene of the piles. In cases of highly tense and irreducible hemorrhoids, he advises that the operation should be done in two stages: first, dilating by means of the fingers alone, and, some days later, proceeding with instrumental dilatation.—*London Med. Record*, May 15, 1882.

INTER-CRICO-THYROID LARYNGOTOMY.—At the meeting of the *Société de Chirurgie* held April 26, 1882, M. NICAISE read a report on the work of M. Richelot on this subject, and a second report on M. Krishaber's work with the same title.

M. CHAUVEL recognized the difficulties alluded to by the reporter, and cited a recent case where it had been almost impossible to insert an ordinary tracheal canula.

M. DÉSPRES mentioned that the first suggestion of the advantage of incising the cricoid was due to Boyer, but since then the incision had been nearly entirely abandoned, except in exceptional cases, where a modified incision was employed. Nélaton proposed the resection of a part of the cricoid cartilage, and M. Déspres published in 1861, in the *Gazette de Hôpitaux*, an account of a case so operated on by Nélaton for œdema of the glottis occurring in pregnancy. M. Déspres had himself, also, performed inter-crico-thyroid laryngotomy for a case of polypus of the larynx, and he recognized the advantages of the operation as facilitating subsequent manipulations in the larynx, or for the removal of foreign bodies, but thought it was unsuitable where it was desired to allow a canula to remain; and he cited a case where the presence of the canula rendered deglutition so painful that the cricoid had to be incised. He is therefore resolutely opposed to the operation.

M. VERNEUIL, on the other hand, is a warm advocate of this method; he believes it to be easy of performance, exempt from the inconveniences and dangers of tracheotomy, and is often the only operation possible; and he has also found that ordinarily the permanent use of the canula is not objected to by the patients. He performed the operation in a case of epithelioma of the larynx, and the patient wore the tube for twelve months without any inconvenience; he also had a similar result in a case of epithelioma of the pharynx, which necessitated the opening of the larynx from the suffocative attacks following the great glandular enlargement. This patient, who is still alive, suffers no annoyance from the presence of the tube, and can even speak without closing it. He had employed the thermo-cautery in these two cases, and not a drop of blood had been lost. In the second case the neck was extremely short, and it was impossible to extend the head without causing suffocation, so rendering the ordinary operation of tracheotomy inapplicable. He thought, however, it should be remembered that the crico-thyroid membrane might be exceptionally elastic, and so prevent the entrance of the canula.

M. FARABEUF had performed this operation fifty times on the body of adults and old people, and had found that the operation, as regards difficulty, was not comparable with tracheotomy. MM. MARC-SÉE, LANNELONGUE, and POZZI also spoke in favor of the operation.—*Le Progrès Médicale*, April 29, 1882.

ABLATION OF FUNDUS UTERI BY ABDOMINAL SECTION.—At the meeting of the Surgical Society of Ireland, held April 14, DR. ATTHILL read a paper on ablation of the uterus, in which, after contrasting the various operations in use for the partial or complete removal of the uterus, and the results obtained by different operators in each method, he gave the details of a case in which he had recently performed a modification of Porro's operation. The patient, a woman aged 58, was first seen by Dr. Atthill in October, 1881. The os and cervix uteri were healthy; but the fundus was enlarged, the sound passing two inches and a half. A clot of blood was daily expelled from the uterus when the pain came on. Not being certain of the condition of the fundus uteri, Dr. Atthill dilated the os and cervix, but found no tumor, as he had partly expected from her previous history. He, therefore, concluded that the disease was malignant, and advised removal of the uterus above its insertion into the vagina. The operation was performed on January 16, 1882. An incision commencing one inch above the umbilicus served to open the pelvic cavity; the fundus uteri was seized, whilst a ligature was passed round the suspensory ligament at either side. The ovaries were found atrophied, but were not removed. A ligature was passed round the neck of the uterus; the fundus cut off; and the raw surface of the stump was touched with the actual cautery, and allowed to go back into the pelvis. The wound in the abdomen was then sewn up. The operation lasted an hour and a half. At 7 P.M. on the day of operation, the temperature was 99°, and the pulse 108; and within twenty-four hours the woman died. The walls of the fundus uteri were thickened and epitheliomatous; and the stump, which had been thrown back into the pelvis, was not free from epithelioma. This was the first case of epithelioma of the cervix uteri which he had seen. It was, therefore a rare affection; so that he was not certain of the exact nature of the case up to the end of the operation. He regarded the operation by abdominal section as a safer one than that through the vagina, though the latter was usually done for epithelioma.—*Brit. Med. Journ.* May 27, 1882.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE, ... $5.00.
SINGLE COPIES, ... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made at the risk of the publishers, by forwarding in REGISTERED letters.

Address, HENRY C. LEA'S SON & CO.,
NOS. 706 & 708 SANSOM STREET,
PHILADELPHIA, PA.

SATURDAY, JULY 15, 1882.

RECENT CONTRIBUTIONS TO THE THERAPEUTICS OF MALARIAL DISEASES.

UNTIL we get some exact information regarding the nature of that mysterious miasm—malaria—our therapeutical resources will be largely empirical. Guided partly by more exact notions derived from the study of its physiological actions, and partly by clinical experience in its use, we now employ quinia more accurately and efficiently than was possible a few years ago. Not to speak of such well-worn topics as the antipyretic action, and the administration of large doses, we will ask the attention of our readers to the subcutaneous injection of quinia, which, although not a frequent mode of applying the remedy, is sometimes of immense utility, as in pernicious intermittent and remittent fever, and in obstinate cases of the ordinary forms. Exceeding difficulty has been encountered in the preparation of a suitable solution. Quinia, in an undissolved state, and in acid solutions, has caused great mischief. The hydrobromate, originally proposed by Gubler, possesses several distinct advantages: it is comparatively soluble in water, produces very little local irritation, and is effective. It is soluble in the proportion of 48 grains to ʒiv, so that 20 minims contain 4 grains. A new compound salt of quinia and urea has been introduced recently. This proves to be more soluble than any other preparation, and is less irritating, no after-redness and swelling occurring. It seems to be soluble in the proportion of 50 per cent., that is, a saturated solution in water will contain one-half by weight of the salt. The quantity of urea—somewhat less than one-tenth—which is present in the compound salt is not objectionable. The name by which it is known is sufficiently complicated—*quinia bimuriatica carbamidata. Quiniæ et ureæ bimurias* expresses the composition, and might, therefore, be substituted for the more difficult and confusing original title.

Numerous remedies have been brought forward as substitutes for quinia, and, indeed, so closely are the chemists approximating to it in composition that an artificial quinia, produced by synthesis, may be expected in a short time. Resorcin, hydroquinone, pyrocatechin, and chinoline are recent products of the chemist's art. Of these, chinoline has excited the deepest interest, because itself, a derivative of quinia, approaches nearly to it in composition. The confident expectations at first entertained that in this we had a remedy of value nearly equal to quinia, are not supported by a larger clinical experience. It has proved very irritant to the stomach, is depressing, and greatly inferior to quinia in antiperiodic power. All of this group—the dihydroxol-benzol group—possess more or less of the antiseptic, antipyretic, and antiperiodic power, but they are far less effective than the cinchona alkaloids.

Carbolic acid possesses some valuable properties as a remedy in malarious diseases. The highly irritable stomach of acute malarial poisoning is usually quickly relieved by small and frequently repeated doses of carbolic acid. Fifteen years ago, Dr. Tessier, of the Mauritius, announced that intermittents are rapidly cured by the subcutaneous injection of three-quarters of a grain of carbolic acid, dissolved in twenty minims of water. This observation attracted but little attention; yet it is true, although there may be limitations. No exact observations, on which a rule of practice may be formulated, have yet been made; but the fact may be stated that simple intermittents, without lesions of the spleen and liver, are often cured by the subcutaneous injection of carbolic acid. These injections give but little pain at the moment of introduction of the needle, and this pain is followed by anæsthesia. To obtain sufficient curative results, they should be inserted about three times a day during the intervals between the paroxysms.

Recently the alkaloid *pilocarpine* has been used to abort the ague. If administered at the moment when the first chilliness, or other disturbance, indicates the onset of the paroxysm, the sweating stage is at once inaugurated, thus preventing the chill and fever. The quantity of the nitrate or muriate of pilocarpine necessary to effect this, will range from one-eighth to one-quarter of a grain, subcutaneously, for an adult. The vaso-motor and cardiac depression which succeeds to the preliminary stimulation must not be forgotten in an estimate of the probable results. Although by this practice an

impending intermittent may be aborted, it does not follow that subsequent attacks will be prevented. In some instances, it appears, an intermittent has been arrested by a single administration of pilocarpine. Thus far there has been no published experience on the use of pilocarpine in pernicious malarial fever, in which, indeed, it promises a high degree of utility. *Apropos* of this formidable condition, we should not fail to mention the very great utility of *amyl nitrite*, subcutaneously, in the algid stage of pernicious fever. From two to five minims may be injected, and repeated at intervals determined by the cessation of the effects. This practice serves a double purpose: the remedy substitutes warmth of the surface and an active circulation for the coldness and depression, and gives time for obtaining the full effects of quinia.

Within a few years *iodine* has come to be regarded as a remedy for malarial diseases, of considerable value. As compared with quinia, it is relatively more efficient in chronic than in acute malarial poisoning. Compared with quinia, and the members of the benzol group above mentioned, iodine takes rank next after quinia. The tincture, the compound tincture, and the compound solution, are the preparations usually employed, and of these, the last mentioned is least objectionable. Iodine agrees with the other remedies used against malarious diseases in antiseptic power, but differs from them in having no antipyretic action. This fact casts a much-needed illumination on the nature of the causes producing malarial disease, indicating that the *materies morbi* is a ferment or a minute organism. The action of iodine on albuminous substances, serves to indicate the nature of the effect it has on germs and ferments. Although iodine solution, promptly administered, will cut short a considerable proportion of intermittents, it has not the antiperiodic power of quinia. It has an important place as a remedy for the complications of malarial fevers, for the enlarged spleen, the congested liver, and the pigment formation and deposit. It is good practice to utilize the effects of carbolic acid and of iodine in the treatment of these complications, and as aids to the curative action of quinia. For example a combination of the two in small quantity and frequently repeated (℞. Tinct. iodinii comp. ʒij; Acidi carbolici, ʒj. M. S. One drop every hour or two) is an efficient means of checking the vomiting, which is often a most embarrassing complication of acute malarial poisoning. Whilst it thus prepares the way for the stomachal administration of quinia, it exerts no little antiperiodic power. If full doses of quinia are given to prevent the febrile paroxysms, and in anticipation of them, iodine and carbolic acid can be administered in the intervals. Beside the internal use of iodine preparations, the local application of the official ointment of the red iodide of mercury is in a high degree efficient as a remedy for enlarged spleen and liver. This practice, derived from the physicians of India, should be carried out with attention to certain details enjoined by them. A piece of the ointment, the size of a pea, is rubbed in thoroughly over the whole splenic or hepatic region, the part being exposed to the direct rays of the sun, or to the heat of a bright open fire. After one or more frictions with the ointment, the epidermis shrivels and is detached, leaving the true skin somewhat red and irritable. Applications must be suspended until the skin is in a condition to bear them. The number of applications required cannot be stated beforehand, but that they are effective in reducing the size of the enlarged spleen, and in diminishing the congestion of the liver, has been proved by an abundant clinical experience.

Within a few years past *eucalyptus* has been brought forward as a remedy for malarial diseases, and at one time quite an exaggerated estimate of its powers was current in the medical profession and in the community. It soon found its proper place as an adjunct to more efficient remedies, and as a tonic and restorative after malarial attacks had been arrested. Within these limits it is useful, but as the principal remedy it is far inferior to some of those mentioned above.

SUMMER SPORTS.

We hail with not a little pleasure the increase of out-door, and, therefore, especially of summer sports and pastimes among us. As a people, we work too long and too intensely. Time was when every one was expected to be at his business from early till late. Close rooms in winter, hot rooms in summer, made havoc with health. When business did not drive the man, the man drove his business. Little, if any, time was given to recreation. Saint's days we have none, and patriotic holidays are few and far between.

True for the men, this state of things was truer still as to women. After a girl reached an age and a size when modesty forbade her indulgence in the sports and games of children, what was there for her to do? She could play with "grace hoops" or battledore and shuttlecock, but soon tired of them, even if she ever began them; or could ride, which was expensive and often impracticable; or could walk, provided she had company: the result was that practically she sometimes walked to school and back, or to do a little shopping, attended to a few in-door household duties, studied, read novels, went to parties, to church, to places of amusement, married, and became at once both a mother and an invalid.

We are glad to recognize a change within the last score of years, and especially, perhaps, the last five or ten. Out-of-door sports and games have grown steadily and rapidly in favor. Cricket and base-ball, rowing and archery, croquet and tennis, have made many converts, and the young men of our cities—for it is of our city population that we are especially writing—are losing the pallor and leanness which was their wont, and are gaining in color and weight and freshness.

Such games do far more than merely effect a physical development. Their mental and moral influences are quite as important. A good cricketer, other things being equal, has a manliness developed in him that is worth a deal. Bodily vigor breeds independence of character. The ability to defend the weak predisposes to the chivalric virtues. Alertness of observation, preciseness and delicacy of muscular co-ordination, decision of character, personal bravery, generous rivalry, and all the better social qualities are developed by such sports. And these will tell in sterner times when the strain of accident or misfortune comes and tests the stuff we are made of.

But it is a still greater boon for women. Some of the lately introduced or lately revived sports have been happily vigorous enough for men, yet moderate enough for women, and so the pleasantest of all athletic conditions is realized when both can join to mutual advantage, the refining influence of the one and the manly strength of the other, each exerting a wholesome influence. No one objects to co-education of this kind.

"Out-door Clubs" are the order of the day, and their objects are as excellent as their name is appropriate. No better means of developing the health and strength of the present generation, and with it that of the next, have been devised. Their number and their advantages should be largely increased. We have often wondered why the English game of bowls has not been introduced on some of the beautifully smooth lawns to be seen on every hand.

Those who do not frequent such clubs take to similar games in the park or on their own lawns, and so gain health and happiness, good lungs, good stomachs, and good muscles. Others join "walking clubs," and explore the hidden nooks in the park and discover beauties no carriage can reveal. Nature is a shy beauty that must be wooed and won. Others again have formed the more pretentious clubs for systematic mountain exploration and improvement, such as the Appalachian Club in the White Mountains, and a similar one at the Delaware Water Gap. We are glad to see also that women are asserting their rights to the oar and the quoit, as well as the mallet, the bow and the racket. To foot-ball and fishing, the gloves and the foil, they will probably remain strangers in spite of what we are taught by a modern artist of the lessons the Roman women learned of the gladiators, and we do not wish to see Amazons in our drawing-rooms.

No class of women need development of the muscular and the respiratory systems more than growing school-girls, and as akin to the subject, we must urge a wider and more thorough introduction of the beautiful and graceful system of calisthenics recently devised and perfected. Not once or twice a week, but every day at least a half hour should be given to such exercise. In time we hope the American woman will not only have legs, but know how to use them; having a back, will be unconscious of it; and in time of emergency be able to swim or to row, to shoot or to climb almost as well as her brother.

"ALLOPATH."

"PUTTING away the 'Pathies" is the title of an editorial in a late number of the *Century*. It fairly represents the misnomer which chiefly the homœopaths have fastened on the regular profession; and the wrong idea which the public have of our position. At the late meeting of the American Medical Association at St. Paul we are glad to see that a protest was entered as to the use of the word "Allopathist." Homœopathy is a "'pathy;" regular medicine is not. "Allopathy" implies the doctrine of "*contraria contrariis*," which we spurn with as much contempt as we spurn that of "*similia similibus*," each being equally false.

We hold to no "exclusive dogma," save that it is our duty to cure disease as quickly and as safely and as happily as possible; no "pathy," save sympathy with the suffering and the injured. We maintain no other position than that of truth scientifically ascertained. We resent any other title than that of "physician."

The profession know no rules by which to administer any remedy but those of experience or induction from physiological and pathological research. If a remedy has been found to be useful in certain given conditions in one man, it will probably be useful in another, and after trial we seek either in the man or the medicine the reasons of its success or failure and act accordingly: if by investigation on man, or the lower animals, it is ascertained that a remedy produces certain effects, we may infer that it will be suited to combat disease when we wish to produce similar effects. Even here experience must be the absolute and final arbiter.

We are the true eclectics. We give any and all remedies, in any and all doses; we are at liberty to use aconite or mercury, hepar sulphuris or quinia; the only proviso is that it be on the avowed basis of experience or research, as already explained, and

not that like cures like, or that the smaller the dose the greater the effect.

The time has come for the whole profession to reject the misnomer so put upon us, and to proclaim its use as an error and a gross offence—all the more offensive because it is erroneous.

THE REGISTRATION OF PHYSICIANS.

THE Legislature of Pennsylvania a year ago passed a law requiring all physicians to register their names and residences with the prothonotary of each County, together with the authority under which he or she practices, *i. e.*, a recognized diploma, or evidence of ten years' practice.

Dr. S. B. Hoppin has just issued a little book giving the names, residences, office hours, place and date of graduation of each physician in the County of Philadelphia, and has classified them according to the various schools of practice.

The total number of all kinds is 1548, of whom the University of Pennsylvania leads with 551 graduates, and the Jefferson School with 437. Without diplomas there are 52.

To encourage any of the graduates of last spring who may think this "a good place to settle in," we simply desire him to determine the quotient when he divides the 850,000 of the population by the 1548 physicians to be supported by them, and to ask himself whether he thinks a constituency of 500 apiece, less the larger share absorbed by the favored practitioners, can do it.

But we have referred to the Register for another reason. It will be a convenient way of determining the professional position of every medical man in the County as determined by himself. Irregulars of all sorts who have graduated, it may be, at regular institutions, may be recognized at a glance.

ILLEGAL PRACTITIONERS.

WE learn that registration has been refused, in this County, to about 75 persons, all of whom are now *illegal* practitioners. What is the profession going to do about it in all the counties of the State? If nothing be done, wherein lies the good of registration?

Only two ways exist by which these pests are to be banished. It may be left to individual action. Possibly the fine of $100 in each case, $50 of which goes to the prosecutor, may be an inducement sufficient to secure their prosecution; or, secondly, the profession as a body, and represented by the various County Medical Societies, may prosecute them. We urge most earnestly that they shall do so. They owe it to the public which is being duped and plundered by these vampires contrary to all law and right; they owe it to themselves as members of a learned and honorable profession to root out from among them such pretenders to science, who disgrace the profession and every one in it. The expense, which has always to be considered, would be but trifling when compared with the good done to the community, and the fines would recoup the Societies to some extent. The prosecution of a dozen such illegal practitioners in this city would put the other three score to flight, lest they too come to grief. Action should be speedy and rigorous.

THE TRICYCLE.

THE doctor's "gig," or "chair," or "one-hoss shay," it seems, may go to the wall. These homely and inexpensive means of locomotion are in danger of being thrust aside by the tricycle, according to *Chambers' Journal*. When in London, last summer, we were struck by the ease and speed with which many persons passed on their way, evidently not for pleasure, but on business, on this to us rather novel vehicle. Even at night, the protecting red light made their use perfectly feasible. Doctors and postmen seem to have taken very heartily to their use, and in many parts of England, in which railway facilities are very limited, they have supplanted the horse to a large extent. The traveller, with ample baggage, can make six to ten miles an hour, without undue fatigue, over the splendid English roads; and the "sociable" form carries two—as may be seen in *Punch*.

But a late improvement really makes the tricycle a possibility. One of the first uses M. Faure made of the storage battery was to propel such a machine at ten miles an hour. With improvements sure to come, we see no reason why the electric tricycle should not become a favorite means of travel, at least, where streets and roads are good. Would that we could say that we saw as good reason to hope for an equal improvement in the highways.

MAYOR KING, of Philadelphia, has shown that the lives and comfort and money of a community can be considered on the "glorious Fourth" as well as on other days.

For two years now we have been spared fire upon fire; the sick and the well have had relief from the pestiferous fire-cracker; and life and limb have been spared. The toy-pistol has had no victims, and the accident- and death-roll at the Pennsylvania and other hospitals have shown no dreadful list of casualties such as we have been accustomed to for years.

Patriotism can and must find other means of expression than the maiming and death-dealing modes hitherto in use. We commend the example to other cities.

SOCIETY PROCEEDINGS.

THE MAINE MEDICAL ASSOCIATION.

Thirtieth Annual Meeting, held at Portland, June 13, 14, and 15, 1882.

(Specially reported for THE MEDICAL NEWS.)

TUESDAY, JUNE 13TH.—The Thirtieth Annual Session of the Maine Medical Association opened in the Council Chamber, city building, at Portland, at 10.30 o'clock A.M., the PRESIDENT, DR. A. K. P. MESERVE, of Portland, in the chair.

The morning session of the first day, after prayer by Rev. J. P. Warren, of Portland, was devoted to the transaction of

MISCELLANEOUS BUSINESS,

the appointment of various committees, hearing the reports of the Treasurer, the Visitors to the Medical School of Maine, and the Portland School for Medical Instruction.

The *Report of the Treasurer*, Dr. A. S. Thayer, of Portland, showed the financial affairs of the Association to be in every way prosperous.

From the committees appointed *to visit the "Medical School of Maine" and the "Portland School for Medical Instruction,"* the reports were highly satisfactory, and testified to the thorough manner in which the duties assigned had been performed.

The curriculum, methods of study and instruction, and the results of the labor of instructors and students, as evinced by recitations, and the final examinations for degrees, were carefully and fairly criticised. Special praise was accorded the instructors in both these schools for their efforts in the direction of a higher standard, by preliminary entrance examinations, longer terms, and a scale of high marks.

The AFTERNOON SESSION opened at 3 o'clock, DR. B. F. STURGIS, of Auburn, in the chair.

In accordance with a resolution of the Society, adopted in 1878, the retiring President, Dr. Meserve, then read

THE ANNUAL ADDRESS.

After a few introductory remarks, the speaker alluded to the sad death of his predecessor, Prof. Wm. Warren Greene.

The Association was then congratulated that its members had labored so earnestly and successfully to keep pace with advancing medical science, and attention called to the practical benefits which had resulted from a strict enforcement of the rule to allow questions of ethics and personal relations to be taken from the Board of Censors, and discussed only by a *unanimous vote.*

It is often difficult—almost impossible, in view of the vast bulk of medical literature, and the countless aids to professional and scientific advancement—to solve the problem of how to best select and appropriate those of the most advantage. Each must determine for himself, but by careful inquiry, by the notices and reviews in the medical journals, by a full and free interchange of opinions, the solution may in part be found.

It was urged that the members strive to contribute matters of interest to the general practitioner and avoid too great a tendency to devote more than a fair amount of time to those specialties having interest only for the few.

There is also too great a danger, especially noticeable among writers, of ignoring or but slightly noticing the treatment of disease. This is doubtless occasioned in part by the enormous strides which have been made in biological investigations, and the special branches of normal and pathological histology, but how few, comparatively, are they who to-day are conscientiously and in true scientific spirit investigating the action of medicines upon the human economy! This is an important field, in which great and successful labor yet remains to be wrought. "Let us give due prominence to the art of medicine."

So little success had attended previous efforts to secure legislation favorable to the elevation of medical practice, or the enactment of needed sanitary laws, that further recommendations seemed useless; but in 1881 a law was passed regulating the practice of attorneys, and bills of interest to the medical profession may perhaps in future meet with less opposition. In truth, the demand for laws of registration, or for otherwise preventing irregular practice, must come from the people whom it was the duty of our profession to so enlighten that they might understand the difference between an educated physician and an empiric. They should clearly understand the definition and true bearing of the term "*regular* physician," and know that we entirely disclaim any such title as "allopath," or any designation whatever.

Expert testimony should only be given at the request of the Court, or the Court itself should be arbitrator. Legislation in this direction is imperative, as preserving the good name of the profession, and to this end the Association ought diligently to labor. As a State Board of Health is yet a thing of futurity, the Association must find what consolation it may in the passage of the anatomical bill enacted in 1881, until the preservation of health and life may seem at least of equal importance with the aspirations of politicians.

To the efforts of the Association has been due in no small degree the past elevation of the medical profession of Maine to a higher standard of usefulness and to a nearer approach to the ideal physician, whose presence always brings comfort and inspires confidence among the unfortunate and afflicted.

After a vote of thanks to Dr. Meserve for his able and instructive address, DR. W. K. OAKES, of Auburn, read a paper on

THE ADMINISTRATION OF ETHER.

In the consideration of this subject, he presented three divisions:

1st. What class of cases are suitable for its use?

2d. What inhaler is the best for general use?

3d. What rules or methods are to be observed in the course of its administration?

In answer to the first, he stated that, except in cases of extensive valvular lesions, or advanced stage of phthisis, he had never felt obliged to deny a patient the benefit of ether, and even then thought the risk from ether much less than the probable shock.

Second. The inhaler, which in his hands seemed best to meet all requirements, was a cone rolled up from alternate layers of towel and thick paper, and provided with a wad of cotton; it was inexpensive, saved ether, and was easily constructed. He had also used the thin folded towel covered by dry ones if necessary, but found it inferior to the method mentioned.

Third. The doctor would urge more uniformity in the manner of administration; considered it unfortunate that no more explicit and definite instruction was given students on this subject.

Complete anæsthesia is by no means devoid of danger, and calls for the greatest skill and caution on the part of the administrator, who should devote his whole attention to this and this only. The room should be perfectly quiet; the patient should be impressed with the necessity of taking full and deep inspirations, and of keeping in mind all the time the last instruction to "keep perfectly quiet;" and, having loosened the cloth-

ing about the waist and throat, the saturated cone should be gradually approximated to the face, allowing a free admixture of fresh air, until the anæsthetic begins to manifest its effects.

The choking or coughing stage may be obviated by a breath of fresh air, and the tendency to swallow the tongue, by keeping the head bent well back. As little force should be used as possible.

His attempts at prevention of vomiting had been attended with little success. Had failed with bromides —hypodermics of morphia—and often after having prohibited solid food for several hours previous.

In all cases demanding severe operations, the anæsthesia should be complete before beginning. Some minor operations, such as extraction of teeth, and incision of felons, might be made at the moment of the first impression. He thought the danger from shock producing heart failure very slight with ether in such small operations, as compared with chloroform. More dependence is to be placed upon the respiratory movements, than the force and frequency of the pulse, as indicating the condition of the patient. If cyanosis threatens, and a few whiffs of fresh air do not revive the patient, Sylvester's method of artificial respiration should be at once employed.

A detailed record of thirty-one fatal cases from ether, unmixed with any other anæsthetic, shows that eleven died within fifteen minutes after the commencement of the operation, when but a small amount of ether had been taken. Five of them died in from an hour and a half to forty hours after completion of the operation. Fifteen were under forty years of age, and sixteen over forty. The youngest was fourteen, and the oldest over eighty.

No record of deaths in dentists' chairs was reported. He believed that at such times a physician should always administer the ether.

In concluding, he said he hoped the discussion might bring out the experience and practice of others in administration, management of accidents, prevention of nausea or vomiting, and the use of agents other than ether.

DR. HUNT recommended, as a preventive of vomiting, the administration of a full dose of some alcoholic one hour before giving the ether.

DR. GORDON preferred to give the ether on an old towel, folded, allowing a free admixture of air. By this method, he claimed that the administration was easier, and more rapid. He very rarely spent more than five minutes in etherizing any patient; oftener consumed from three to four minutes, and an ounce or two of ether.

DR. GERRISH preferred the towel to the cone, though it was wasteful of ether. He had not had any success in quick administration, but averaged from ten to fifteen minutes. He thought the administration of from seventy to eighty grains of bromide of sodium, during the twenty-four hours previous to operation, had in his hands been successful in preventing emesis.

DR. O'BRION said the exigencies of ether could not always be guarded against in a busy country practice. As a preventive of waste, he would cover the ether towel with one wet in water. Believed emesis to be oftener produced by paralysis of the pneumogastric than by a full stomach.

DR. CROOKER relies much upon carbolic acid.

DR. A. J. FULLER, of Bath, reported

A CASE OF UNUSUAL ACCUMULATION OF ASCITIC FLUID.

The patient, a married lady, sixty-five years of age, was tapped, in all, forty-three times. The first operation relieved her of twenty-two and a half quarts of clear serum; the last operation was on February 12, 1882, one year and nine months from the first tapping, during which time seven hundred and ten quarts of fluid were removed. The patient died two weeks from the date of the last operation.

REPORTS.

DR. SANBORN, of Augusta, read his report as delegate to the Connecticut Medical Society; and DR. E. EUGENE HOLT, of Portland, read a brief account of his visit to the Seventh International Medical Congress last August.

CONGENITAL MALFORMATIONS.

Among the voluntary reports of interesting cases was one by DR. O'BRION, of Bristol. A female child was born, after an easy labor, with what appeared to be an intra-uterine amputation of the left forearm. Close examination revealed an otherwise perfectly formed child. But the deformity proved to be not an amputation, but the substitution of a well-formed ankle and foot for a forearm. This was of normal size, situated at what should have been the elbow-joint, presenting its plantar surface forward. The child is now six years of age, and perfectly healthy. The supplementary foot has increased not quite in proportion to the other members, but is destitute of any bony structure; in other respects it is a perfectly formed foot.

DR. ADAMS, of Litchfield, reported a case of a child born with fractures of all the long bones, attributed to an accident during the third month of pregnancy.

The EVENING SESSION opened at 8 o'clock with a paper by Dr. E. EUGENE HOLT, of Portland, on

SYMPATHETIC DISEASES OF THE LACHRYMAL APPARATUS.

After a brief review of the anatomy and physiology of the lachrymal region, the author passed directly to speak of epiphora, regarding it as dependent upon, (1) affections of the lachrymal gland itself; (2) granulations or foreign bodies on the lid or in the retro-tarsal fold; (3) displacement, obstruction, or obliteration of the semilunar fold and caruncles; (4) stricture of, or foreign body in, the canaliculus; (5) Inflammation of the lachrymal sac; (6) stricture of the nasal duct; (7) naso-pharyngeal catarrh, polypus or foreign body in nasal cavity, granulations or adenoid growths in the vault of the pharynx; (8) ametropia; (9) paresis or paralysis of the facial nerve; (10) mental influences.

Statistics were presented compiled from fifty-one cases of lachrymal disease, illustrating the operation of these different causes. When the epiphora had resulted from ametropia, the excessive lachrymation had been greatly or entirely relieved by the application of glasses to correct the optical defect.

Conservative treatment had been adopted in the writer's first series of cases of lachrymal disease, and radical treatment in the second; his preference was decidedly in favor of the milder measures.

Lachrymal abscess was often mistaken by the general practitioner for erysipelas. If seen early, the trouble might be averted by hot water, hot fomentations, leeching, or steaming; if not, then recourse should be at once had to the knife, when an opening might be made through the canaliculus, or by Agnew's method, entering the sac by a Beer's cataract knife, through the mucous membrane at the angle behind the canaliculus just in front of the caruncle; the sac should be opened through the skin only as a last resort.

It was stated that the milder treatment of this distressing affection was strongly urged by Fitzgerald and Swanzey, of Dublin, as well as by Power and Bozeman, of London, and many Continental ophthalmologists.

In the discussion following, DR. SPAULDING thought that the prognosis in cases of diseases of the lachrymal

apparatus depended largely upon the locality of the obstruction. If the latter were situated in the puncta, canaliculi, or even at the entrance to the sac, a favorable result could be almost surely relied upon. But when the obstruction, stricture, or inflammation was deep seated in the sac itself or in the nasal duct, the affection was liable to be very obstinate. (This point was elucidated by various cases reported.)

In slitting open the canaliculi we should be careful not to make the incision outward, but inward, so as to form a reservoir for the tears. Large probes were occasionally beneficial, but their long-continued use might cause extensive inflammation in the neighboring tissues.

In blenorrhœa of the sac, local applications (by means of the syringe) of boracic acid and different astringents were always indicated.

It is bad surgery to apply poultices over an inflamed lachrymal sac. Two cases of lachrymal fistula dependent upon this treatment were reported; under all such circumstances the surgeon should insist upon the knife, for he could then open where he chose and make a smooth incision, which could be kept clean and thoroughly drained.

DR. STANLEY P. WARREN, of Portland, presented a practical paper on

"TREATMENT OF THE PLACENTA AFTER ABORTION."

The writer classified abortions under four heads, advocating primary extraction of the placenta without leaving the result to nature, observing, of course, all proper precautions with reference to shock and hemorrhage.

Class I.—Sudden flooding, cervix open, severe shock, and it is unknown whether the placenta has been expelled or not.

Class II.—Moderate hemorrhage; the fœtus has recently been expelled; the cervix open, and the placenta within reach; general condition good.

Class III.—The fœtus has been expelled for some days; the secundines are retained; the lochiæ are fetid and some form of septic inflammation is present in the pelvic cavity.

Class IV.—There has been more or less flooding; fœtus has been expelled; cervix is closed, and the placenta cannot be reached by the finger; general condition good.

Cases were cited illustrating each of these divisions, and facts presented as to the subsequent condition and labors of these patients.

For the first class the Doctor recommended procedures which should relieve shock and check hemorrhage, and as soon as reaction was well established the contents of the uterus, if any, should be removed.

In the second class there appears to be no question as to the propriety of immediately evacuating the uterus if the placenta is free and can be removed *without preliminary dilation of the cervix.* It is to be regarded as simply a foreign body. There is less danger of injury to the tissues with the finger than with the curette; it has also the advantage of the sense of touch. The curette, on the other hand, causes less pain and may be used with or without the speculum; has not found the ovum forceps as safe as the curette, still less than the finger, and ought to be used very cautiously in the uterine cavity.

In the third class, where we have present or impending some metritis, no good reason obtains why the uterus should not be, within 24 hours, relieved of its contents and thoroughly cleaned; the cervix is usually patent and requires no dilation; a dull curette, followed by intra-uterine, not carbolized, injections, will accomplish every desired object in the way of removal. The quicker the focus of infection is taken away, the less is reparative action delayed and septicæmia to be expected.

In dealing with class third, when the fœtus is expelled, but the placenta shut up in the uterine cavity, obstetricians must choose whether they will "do nothing," relying upon rest and opiates, or mechanically dilate the cervix, perhaps, with a sponge tent, and, as they say, "let nature take its course," or they *may remove* the placenta within twenty-four hours after the expulsion of the embryo, using dilators for some hours before operating, or dilating with finger, and immediately extracting.

On these points of procedure the most distinguished obstetricians and gynecologists in the country differ.

It has been urged in objection—

1. It is unnecessary, since the vast majority of patients do well if let alone.

2. It is the finger, curette, or forceps that does the damage, rather than the retained placenta.

3. It is very difficult, perhaps impossible, to entirely remove an adherent placenta, and septicæmia can be caused by a placental tuft as surely as by the entire organ.

To these objections the Doctor replied:

1. Tonic contractions are essential to the arrest of hemorrhage; there cannot be tonic contractions until the placenta is expelled, and the less will be the hemorrhage existing or possible.

2. Anxiety in both patient and physician will be prevented by early completion of the abortion.

3. Time is gained in uterine involution.

4. Absorption of putrilage from retained secundines is unquestionably the most frequent sequel in abortion; when the uterus is thoroughly disinfected, septicæmia is evidently imaginary. Possible accidents from manipulation are not a sufficient reason for permitting a placenta to be removed by decomposition, ignoring the fact that self-imprisonment must be imminent; by early removal, therefore, of the placenta, septicæmia is prevented.

5. Clinically, after abortion, metritis can rarely be traced to direct mechanical violence. If lesions have occurred in the process of extraction, infection in an empty uterus must be slight when compared with one in which the entire absorbing surface is exposed, and covered by a decomposing placenta.

Inasmuch as the session had already been prolonged to a late hour, beyond the usual time for adjournment, this paper did not receive as much discussion as so interesting a subject, and more particularly the merit of the paper itself, deserved.

WEDNESDAY, JUNE 14.

The Association met at 9 A.M., and unanimously adopted the resolution condemning

THE NEW YORK CODE

offered by DR. S. H. WEEKS, of Portland (see THE MEDICAL NEWS, June 24, p. 703).

DR. M. W. HALL, of Saco, read a paper on

RUBEOLA,

illustrated by facts and statistics from his own practice and that of other members.

DR. E. C. HILL, of Lewiston, presented

A CASE OF SEXUAL MALFORMATION

for inspection. The patient, a well-developed child of four years, had presented this abnormality from birth. The clitoris was apparently a penis, though imperforate; the meatus urinarius was situated some distance within the ostium vaginæ, which had been enlarged to admit of a free passage of urine and exploratory examination. The uterus was normal. Subsequently the clitoris was amputated in the presence of several members of the Association.

RESIGNATION OF THE SECRETARY.

DR. CHARLES O. HUNT, Superintendent of the Maine General Hospital, tendered his resignation as Recording Secretary, after fourteen years of continuous service.

In accepting this resignation the Association adopted the following resolution:

Resolved, That in accepting the resignation of Dr. Charles O. Hunt as Secretary of the Maine Medical Association, we tender to him our sincere thanks for the able and efficient manner in which he has performed the duties of the office, and regret exceedingly that he feels obliged to resign his position on account of pressure of other business engagements.

Drs. C. W. Johnson, of Machias; Dr. Decker, of Fort Fairfield; and Dr. George W. Stoner, of the U. S. Marine Hospital Service, were introduced to the Association and invited to participate in the discussions.

DR. JAS. A. SPALDING, of Portland, read a paper on

THE EXTRACTION OF CATARACT,

showing by diagrams the various methods of making the incision, of performing the iridectomy, of opening the capsule, and of removing the cataractous lens from the eye.

Several cases were referred to, in his own practice, showing how the operation might miscarry from no fault of the operator. "We are apt to forget that an eye affected by cataract is no longer young, no longer healthy; on the other hand we should be ready to avail ourselves of the result of experience and practical study, in order to save an eye which might have undergone inflammation after a perfect extraction of the cataract."

Great stress was laid upon the careful performance of every step in the operation, as well as upon the necessity of absolute rest subsequently.

The author then mentioned the excellent results which he had lately obtained in several cases in private practice, as well as at the Maine General Hospital, but did not offer any statistics, his figures being at present too small to compare with the larger ones of more widely known ophthalmologists.

MISCELLANEOUS BUSINESS.

The PRESIDENT appointed a committee to revise the by-laws, and report next year.

DR. SANGER'S report on proposed changes in the constitution was accepted, and lies over for action until the meeting of 1883.

DRS. PIERCE, of Freeport, and THAYER, of Portland, reported cases in which a large amount of pleuritic effusion was eliminated by expectoration.

AFTERNOON SESSION. — The Association came together at three o'clock, and resumed its work by welcoming delegates from other Societies.

From the Massachusetts Society were present Drs. Dwight, of Amherst, and White, of Somerville.

Dr. Gibson, of New Hampshire, was introduced as a delegate from the White Mountain Medical Society.

The Association then proceeded to

THE ELECTION OF OFFICERS.

DR. GEO. E. BRICKETT, of Augusta, was elected *President*.

The Nominating Committee reported the following list of officers and appointments. The report was accepted and those gentlemen declared elected.

Vice-Presidents.—Drs. J. B. Walker, of Thomaston, and E. A. Thompson, of Dover.

Recording Secretary.—Dr. Chas. D. Smith, of Portland.

Corresponding Secretary. — Dr. J. O. Webster, of Augusta.

Board of Censors.—Drs. H. N. Small, of Portland; W. K. Oakes, of Auburn; J. M. Bates, of Yarmouth; Wm. B. Cobb, of Standish; and J. D. Nutting, of Hallowell.

DR. BRICKETT, the newly elected President, read a paper entitled

TEN CASES OF AMPUTATION OF THE THIGH.

These operations were made to relieve diseases of the knee-joints, and after gunshot wounds and other injuries.

Two were made with use of "Listerism," and the remaining cases were treated in the old way with silk ligatures and cotton dressing. Recovery was secured in every case.

In his conclusions, the Doctor argued strongly:

1. That there is no need of the carbolic acid spray in amputations.

2. That all hemorrhage should be completely arrested before dressing.

3. That all bleeding vessels should be tied with either *silk* or catgut, and *cut short*.

4. That flaps should be united by the same material, and covered by dry absorbent cotton, or Lister's antiseptic gauze.

5. That drainage is not necessary if the surfaces are *perfectly dry* before approximation.

No drainage was established in any of the cases reported.

And lastly, that operating immediately after injuries, or before reaction follows shock, may sometimes be advisable.

DR. ST. C. O'BRION, of Bristol, then delivered the

ANNUAL ORATION,

entitled *The Young Physician*.

Dr. Byer, of the U. S. Navy, was introduced and invited to participate in the discussions.

DR. L. J. CROOKER, of Portland, exhibited an ingenious instrument to be used as an *exploring or evacuating trocar*.

At the EVENING SESSION DR. F. H. GERRISH, of Portland, reported the results in

TWO CASES OF REMOVAL OF UTERUS AND OVARIES,

the only cases of the kind which he had had, and, as far as he had learned, the only successful cases in the State.

The details of the operations and after-treatment were not given, having been previously reported to the County Society, but the essential facts were stated. The operations were performed to relieve patients of uterine fibroids, and consisted in each case in the removal of the body of the womb, the cervix being tied with silk just above the vaginal junction.

In the first case there was no shock, no hemorrhage, no peritonitis, no septicæmia, the patient slowly regaining her strength, and going to work in a farm house thirteen weeks after the operation. For more than ten months she has done all the woman's work on a small farm, and is in the enjoyment of good health. The remnant of the cervix is felt as a very small projection into the vagina, and there is not the smallest evidence of the existence of any inflammatory products anywhere in the pelvis.

In the second case septicæmia appeared at the end of a week, and nearly destroyed the patient. There was profuse hemorrhage from the vagina at the time when menstruation would have been expected but for the operation, and at the six subsequent periods there has been some profound perturbation of the system, sometimes a high fever, at others a violent hysterical attack, etc., as if nature, being deprived of the organ through which it had ordinarily expressed itself, sought new channels in quite different directions. The cervix

has dwindled, but all around the vault of the vagina is a thick mass of plastic material, exquisitely sensitive, and evidently the result of inflammation.

The patient is still an invalid, but apparently has a good chance of recovery in time. In both cases the ligatures escaped through the vagina.

DR. HOTT read a paper entitled

THREE MONTHS AT THE ROYAL LONDON OPHTHALMIC HOSPITAL, MOORFIELDS,

embodying a description of the institution. The paper set forth some of the methods of operation there in vogue. It spoke of the treatment of ophthalmia neonatorum, so faithfully carried out by Dr. L. Webster Fox, then acting assistant house-surgeon, now of Philadelphia; of Buller's eye-shield for the protection of the sound eye in gonorrhœal ophthalmia; of the treatment of diphtheritic ophthalmia by the constant local application of a solution of quinia (Mr. Tweedy); of the use of eserine, and the different views as to the treatment of sympathetic inflammation; of tobacco amblyopia, and many of the rarer forms of ophthalmic disease.

In the ensuing discussion DR. SPALDING thought that the methods here employed did not differ essentially from those which the text-books laid down. Too much weight has been laid on diphtheritic conjunctivitis, which in our country, outside of the large cities, is so rare that it is doubtful if a genuine case has ever occurred, for instance, in Portland.

Eserine had proved itself dangerous in one or two cases of keratitis, setting up severe iritis. We should always remember that iritis is by no means uncommon in inflammation of the cornea; hence eserine should be used sparingly in the latter disease. Still it is a most valuable remedy; only the physician should generally be entrusted with its application to the eye.

Dr. Spalding could not agree with the views expressed concerning the doubt which had been mentioned as prevailing in cases of threatened or evident sympathetic ophthalmia.

The indications and counter-indications for enucleation had been so carefully laid down in Mauthner's "Sympathetic Diseases of the Eye," that every one should be able to decide upon the proper steps to be taken. Optico-ciliary neurotomy was not considered entirely satisfactory as a prophylactic against the transmission of this terrible affection.

THURSDAY, JUNE 15TH.—DR. J. O. WEBSTER, as delegate to the Massachusetts Medical Society, presented his report.

DR. CHADWICK read a touching eulogy on the late Dr. S. H. Tewskbury.

THE BOARD OF CENSORS

reported at some length, making the following appointments for the next meeting:

Orator.—DR. M. C. WEDGEWOOD, of Lewiston.

Necrologist.—Dr. S. C. Gordon, of Portland.

Also Visitors to the "Medical School of Maine," and the "Portland School for Medical Instruction." The number of subjects assigned for the next meeting is larger than heretofore, and it is hoped the session of 1883 will meet all expectations.

The Report of the Committee on Necrology was received and referred.

DR. GERRISH reported a case of

URETHRAL DIVERTICULA IN THE FEMALE.

He was obliged to catheterize a patient after a difficult parturition and had great trouble in doing so, on account of spasms, as he at first supposed. After prolonged and fruitless efforts, he etherized the patient but succeeded no better; he then called a skilful and experienced practitioner in consultation, who tried for a half hour to introduce the catheter, but in vain. Subsequently Dr. Gerrish discovered that the urethra made a sharp turn forwards, and that there was a diverticulum from each side, one two inches, and the other one inch in length.

After this there was no difficulty in drawing the urine or in entering the diverticula at will. They were not false passages, as the woman had never before had a catheter passed on her.

After the usual votes of thanks to retiring officers, and the city of Portland for use of the rooms, the meeting adjourned to meet at Portland on the second Tuesday of June, 1883.

NEW YORK SURGICAL SOCIETY.

Stated Meeting, April 11, 1882.

DR. T. M. MARKOE, PRESIDENT, IN THE CHAIR.

DR. H. D. NOYES, on invitation, read a paper entitled *A Case of Lodgement of Foreign Body in the Cavities of the Nose, Orbit, and Cranium, where it remained Five Months; Removal by Operation; Subsequent Trephining for Pus in the Brain; Death; Autopsy;* which is published in full in the current number of *The American Journal of the Medical Sciences*, page 45.

DR. POST recalled one of Mackenzie's cases where the patient was able to walk several miles to a surgeon, and after the wound was dressed and recovery had so far advanced that he was quite well, he indulged in drinking, and a fatal inflammation developed as the result of the debauch. The foreign body was extracted during the progress of the fatal inflammation.

DR. R. F. WEIR remarked, concerning the literature of the subject, that the best account he had found of foreign bodies in the brain was in a prize essay by Dr. Wharton, of Philadelphia, who collected 316 cases, and in 14 of these the foreign body was a breech-pin. Of these 14, 9 appeared to bear out Dr. Noyes' remark fully, that when removed early the patient usually did well, for in every instance the foreign body was removed within three days and in some of them within a few hours after the reception of the injury, and recovery followed in 7 cases. Of the remaining 5 cases of the 14, the breech-pin in one remained 24 days, was not extracted, the wound in the brain healing perfectly, but the man died. In another it remained 28 days, was not extracted, and the man died in consequence of inflammation set up by excessive drinking. In another case reported by O'Callaghan in 1845, the breech-pin remained in the brain one year, and then the patient died from inflammation resulting from intemperance. In another case the foreign body remained 26 days, was three inches long, was extracted, and the patient recovered. In another case the foreign body remained 4 months, weighed two ounces, was extracted, and the patient recovered.

An important point raised by Dr. Noyes was, whether or not surgeons should refrain from interference in these cases. In looking over the list of cases referred to, he was struck by the fact that, sooner or later, where the body was not fixed or immovable, death occurred in consequence of inflammatory action from undue exercise, sudden jars, excessive drinking, etc. It would seem that this class of patients are exposed to danger all the time. This also obtained, though to a lesser degree, in those where the foreign body was imbedded or held firmly *in sitû*. He felt that the risk in a given number of cases would be less from interference, and that the surgeon would be justified in extracting the foreign body whenever met with, observing great precaution to free it carefully and thoroughly from all bony hindrance, so as to permit the extraction to be accomplished easily and without force, and in this way.

to disturb the cerebral end of the missile in the least possible degree. In other words, it should be lifted out, not pulled out.

The accounts presented of the successful removal by Beaumont of a piece of a rocket shaft; by Jamison of a piece of wood embedded four months; by Larrey of the point of a javelin fourteen years in the brain; by Mactier of the blade of a penknife, two inches long, six months *in situ*; and by Turnipseed of a similar foreign body lodged three years, with others equally forcible, encourage surgical opinion and action in this direction.

DR. STIMSON asked if the cavity in the anterior lobe on the right side in the specimen represented the cavity of the abscess evacuated at the time of the operation of trephining.

DR. NOYES said that it did not. The abscess struck at the time of using the trephine was formed about the cyst which enclosed the foreign body. But, from the trephining operation to the time of death, there was a continuous breaking down of brain substance, extending backward towards the middle lobe.

DR. GEO. A. PETERS said that, since the New York Hospital had occupied the present building, there had been a case in its wards similar, in some respects, to the one reported by Dr. Noyes. As he recollected, a man was shooting duck in Jersey; his gun exploded; and the breech-pin was driven into his forehead. It was extracted, and he recovered. Some years ago an explosion of nitro-glycerine occurred in Greenwich Street, and, two blocks above, a milkman was thrown from his wagon, and received injuries, for which he was brought to the hospital, where Dr. Peters saw him two or three hours afterwards, and found that a large fragment of the wagon had been driven through the parietal bone, and an inch or more into the substance of the brain. He was unable to move it; but, by gnawing the bone away with a rongeur, he succeeded in removing it, and the patient recovered.

The PRESIDENT thought that the line of practice in recent cases would be regarded as settled in favor of immediate removal of the foreign body. It seemed to him, however, that Dr. Noyes had suggested an important point upon which the cases cited by Dr. Weir, more carefully analyzed, might throw some light, namely, as to whether it is the duty of the surgeon in cases in which the foreign body has been in the brain for a considerable period without producing any symptoms, to remove the body under the apprehension that certain accidents might occur in the future, or whether it should be left, in the hope that these accidents might not occur or be long delayed.

DR. PETERS said that he should be loth to leave a foreign body in position for much time after he had discovered its existence, believing that the damage which it might occasion by being there, more than counterbalances the risk which might be incurred by any reasonable effort at removal.

DR. WEIR thought that the case reported by Eve, in his "Remarkable Cases in Surgery," supported Dr. Peters' views. In that case the breech-pin entered the ethmoid and sphenoid bones, but the cranium was not involved. It was carried, with much suffering and nasal discharge, by the patient for eight years, when one day attempting to sit upon a chair the patient sat through error forcibly upon the floor. The result was that the breech-pin broke, from the impulse, from its attachments, invaded the cranial cavity, determined a cerebral abscess, and caused death on the eighth day afterwards. In other words, he thought in recapitulation that the risks of leaving the foreign body were greater than those which came from an operation for its removal.

DR. STIMSON thought it desirable, if possible, to ascertain what the effect of the practice was in this case. From where did the pus come at the time of the first operation?

DR. NOYES said that the first operation was simply enlarging the opening in the orbital plate, two weeks after removal of the foreign body. The pus was found just above the orbital plate, and was evacuated by an incision which enlarged the aperture in the dura-mater made by the foreign body; and it was quite probable that the abscess extended back into the brain substance, beyond the cyst. He thought that disintegration was going on about the cyst at that time. During the two weeks there had been discharge of purulent material that was very offensive, and it was assumed, and the light of subsequent experience seemed to show that the assumption was correct, that it came from within the cranium. Before the foreign body was removed, there was only a slight ichorous discharge from the nostril. It was quite probable that the cavity of the abscess might have been reached from the orbital side had he proceeded a little further with the exploration. To attack the abscess through the orbital plate was attended by serious inconvenience for two reasons: 1. The drainage secured is bad. The head lying upon a pillow, the discharge does not easily find a way of escape. The trephine hole is more direct than the opening in the orbital plate. 2. The growth of reparative tissue in the orbit constituted an obstacle to free drainage, aud was also a constant source of embarrassment in the dressings. Dr. Noyes thought that one of two suggestions, or, perhaps, a combination of both, would be advantageous in similar cases. First, it was suggested by Dr. Weir that perhaps it would be proper to try and reach the abscess by removing the orbital edge of the frontal bone with a chisel or other means, and make an opening into the frontal lobe directly at the edge of the brow. The same suggestion has already been made by Berlin.

A second suggestion is that the best evacuation of the abscess can possibly be secured by entire evisceration of the contents of the orbit, because the surgeon in that way gets rid of a large mass of material that obstructs drainage and dressing.

DR. STIMSON thought that the existence of an inch and a quarter of solid brain tissue between the surface and the abscess at the time of the introduction of the drainage-tube, and the entire absence of that tissue at the end of 24 days was rather against the desirability of using a drainage-tube under such circumstances. He thought that an abscess situated at that distance below the surface should be reached through the original orbital opening rather than from above, notwithstanding the greater dependence of the opening made with the trephine.

DR. NOYES remarked that the drainage-tube was kept in place for only three days, and was introduced in accordance with a suggestion made by Dr. Lidell in the American edition of Holmes' "System of Surgery," in his notes to Prescott Hewett's article, as to the propriety of using a drainage-tube.

Dr. Lidell referred to the propriety of using a drainage-tube, as suggested in the American edition of "Holmes' System of Surgery," in his notes to Prescot Hewett's article. Another interesting question was with reference to the point at which the trephine should be applied, and, as already stated, it was chosen in accordance with the suggestion made by Dr. Janeway.

DR. JANEWAY said that the reasons that led him to select the point at which the trephine was applied were, (1) because the direction in which the missile entered, and the course of the track from which it had been removed, pointed towards its lodgement in the anterior lobe; (2) the fact of its having been in the anterior lobe during five months and yet producing no paraly-

sis, indicated that it had rested in a part of the frontal lobe anterior to the motor tract; and (3) the strong probabilities were that an abscess formation would have its centre at the the point where the foreign body had laid, and where in its removal a certain amount of injury had been inflicted upon the brain substance. A paralysis coming on after removal did not absolutely indicate abscess extending back to the motor tract, but it might be due to secondary inflammatory œdema spreading beyond an abscess.

He thought that the paralysis in this case was probably due to a secondary œdema rather than an abscess itself, because he had seen several cases in which paralysis had, without doubt, been produced in that way, because the original tumor, abscess, or injury, had been anterior to that portion of the brain the injury of which gives rise to paralysis.

Besides, if the trephining had been done over the motor tract and drainage was to be effected through the opening, the destruction of brain tissue in the motor tract, which would almost inevitably have followed, would have given rise to permanent hemiplegia.

The œdematous infiltration of the surrounding parts, secondary to an abscess, tumor, or foreign body, should always be kept in mind in estimating the probable cause of paralysis.

Another point of interest, surgical as well as medical, though belonging to a different class of cases, was the liability to the occurrence of abscess of the brain, etc., after the removal of a portion of the periosteum of the skull, and also after rhinoplastic and other operations of a similar character about the head. He had seen one case of rhinoplastic operation followed by abscess of the brain, and another followed by meningitis.

Dr. Knapp thought that Dr. Noyes' suggestion concerning complete removal of the contents of the orbit, could be readily carried into effect without special danger. With reference to tumors in the frontal part of the skull, they were very apt to prove fatal by meningitis.

Dr. Allan McLane Hamilton said that when he saw the patient it was some time after the paralysis had manifested itself, and there was involvement of the motor tracts and certain parts of the tegmentum. He was, however, struck by one thing, the comparative absence of psychic symptoms. Ferrier, Lepine, Baraduc, and others, have presented cases in which decided mental impairment followed injury of the frontal lobes. There was a condition which was symptomatized by a noticeable diminution of intelligence and concentration.

Ferrier's experiment upon monkeys were negative so far as paralysis was concerned, but a marked change was produced in the animal's disposition.

He remembered a case some years ago with extensive destruction of the frontal bone and hernia cerebri in a boy twelve years of age. Large masses of the brain substance were cut off, but there was no affection of intelligence. These two cases are exceptions (but rare ones) to Ferrier's law. According to Meynert, Wündt, and others, the anterior brain is what may be called the seat of inhibitory mental power, and extensive destruction shows this usually.

Dr. Janeway said that, whilst Dr. Noyes' patient would answer questions, and his intellect seemed, upon general observation, to be unimpaired, it was very questionable whether, if placed in his boyhood surroundings, and among his relatives and companions, he would have exhibited his usual mental power. Patients under similar circumstances might answer simple questions and do simple things when called upon; but questions which required a little more thought they were very frequently unable to answer, and then it was that mental impairment was manifested.

He had had a case in which there was greater primary destruction of the substance of one frontal lobe than in the case reported by Dr. Noyes, and yet the man was able to do ordinary kinds of work, and died of multiple embolism of the right anterior, middle, and posterior cerebral arteries, from ulcerative endocarditis.

At the autopsy it was found that there had been destruction of the first and second frontal convolutions, back to within an inch of their posterior extremities, over a space two inches in length, extending from the corpus callosum up to the surface, leaving a cyst two inches across, and partly filled with a plexus of convoluted veins.

The Society then adjourned.

COLLEGE OF PHYSICIANS OF PHILADELPHIA.

Stated Meeting, June 7, 1882.

W. S. W. Ruschenberger, M.D., President, in the Chair.

Dr. William B. Hopkins read a paper on *Tenosynovitis: its Causes, Nature, Symptoms, and Treatment; Based upon an Analysis of Fifteen Cases*, which he defined as an affection usually occurring in the forearm, and characterized by a peculiar creaking of the tendons as they move in their sheaths, depending upon a particular kind of strain to which the muscles belonging to these tendons have been subjected.

The predisposing cause of the affection is the occupation of the individual, and in studying, therefore, fifteen cases, occurring in subjects of otherwise average health, the nature of their employment is worthy of special attention. In three of the fifteen, the disease occurred in men employed in a dyehouse, whose work consisted in wringing the goods, which had been soaked in dye; in two, the patients were weavers, who throw the shuttle from side to side with the index finger of the right hand; one case occurred in a baker, from kneading bread; one in a boiler riveter, from hammering; one in a car-driver, from using the brake; one in an iron-moulder, from continued use of the shovel; one in a plaster-worker, from stirring plaster with a hoe; one in a washerwoman, from using a clothes wringer; one in a laborer, who continued to work after receiving a severe contusion of the forearm from the fall of a heavy iron pipe; and one each in a rope twister, a marble rubber, and a painter.

In contrasting the above-named occupations with many others, requiring far more muscular effort, and giving employment to many more workmen than these, the idea suggests itself that it is not the mere amount of strain to which the muscles and their tendons are put that predisposes to the disease, but rather the kind of effort which is of a tedious, continuous, monotonous sort. On the other hand, trades which would appear likely to furnish subjects for the disease more frequently than those which have been already spoken of, fail to do so. This, in some instances, can be explained. Gold beating, for example, where an eight-pound hammer is used almost uninterruptedly for five hours, and is carried from above the shoulder down to the level of the waist, would seem to contradict this view, as the disease is unknown to one of the largest gold leaf manufacturers; a careful study of the movements of the operatives in performing this work, however, shows that the strain is not upon the muscles of the forearm, but rather upon those of the shoulder and arm; as the hammer descends simply by gravity and returns by recoil from the elastic block, composed of alternate sheets of gold and animal membrane, to a point where the biceps and deltoid muscles complete the elevation.

The exciting cause of the attack is usually the resumption of work to which the individual is thoroughly accustomed, after a shorter or longer internal, when he is out of practice, and when the parts involved in executing special movements have become less actively

nourished; though, in the case of the washerwoman, the clothes-wringer was used for the first time, and the rope twister was doing work that was new to him. In the laborer the attack was of traumatic origin.

Pathology.—The means of determining the exact lesion in this disease are necessarily to a certain extent conjectural, but as the pain and crepitation are coincident in their onset and subsidence, as there is no impairment of motion after recovery has occurred, and as the parts under treatment regain their normal condition in a very short time, it seems highly probable that there is no true inflammatory process at all, certainly none extending beyond the stage of congestion, and that the creaking which exists is due to insufficient lubrication, with consequent dryness, not, as has been supposed, to exudation of lymph. Under rest and counter-irritation the congestion very soon disappears, the synovial surfaces pour out their proper fluid, and the tendons once more move smoothly and noiselessly in their sheaths.

Symptoms.—Soreness, amounting to positive pain upon motion or pressure along the course of the affected tendons, inability to use the part, and the presence of the peculiar creaking, which is communicated to the finger on palpation, are the symptoms which denote the existence of tenosynovitis.

Diagnosis.—From its common seat upon the dorsum of the forearm, this affection may be mistaken for fracture of the radius. The history of the case, however, showing that there has been no blow or fall, as a rule; the quality of the crepitus, which is much softer and finer than that of fracture, and like that of cellular emphysema after fracture of the ribs, or that produced by rubbing two pieces of cloth between the fingers, and the way in which the crepitation may be elicited,—all leave little chance of error. The disease will not be mistaken for a strain of the muscle, if a careful physical examination is made.

Treatment.—From what has been already said, it will be seen that the disease is at once acute, painful, and disabling. It, however, yields, as a rule, readily to treatment; for the patient can seldom work more than a day after he is attacked, and finding that he exhausts the usual home embrocations, without relief, promptly seeks aid elsewhere; this enables the surgeon to institute treatment before an advanced stage is reached and permanent mischief done by a deposition of plastic matter. Absolute rest of all the parts concerned is the most important element in the treatment; a palmar splint, therefore, from the elbow to the tips of the fingers is applied, when the forearm is the part affected. Counter-irritation is next indicated, and may be employed in one of two ways. If the skin is red, a band one inch broad of tincture of iodine should be painted in an oval form around the area over which creaking is felt; while a lotion of lead water and laudanum is applied within this band. In cases where there is but slight creaking, and no redness of the skin, tincture of iodine may be painted directly over the diseased part, without the employment of any lotion. The dressing is re-applied each day, until all pain, tenderness, and creaking have disappeared, which generally occurs at the end of four or five days. After this a roller bandage alone is continued, until the parts have regained their tone.

CORRESPONDENCE.

LETTER FROM BERLIN.

The Berlin Clinics—Profs. Virchow and Frerichs—The Bacillus Tuberculosis.

THE old Berlin student will easily find his way about in the Charité grounds to the well-known clinics, amphitheatres, and post-mortem rooms, as the general disposition of the medical centres has not changed much in the last fifteen or twenty years. Moreover, if from our country, and doubtless from anywhere else abroad, he will receive the same kindly greeting from the same well-known celebrities to whom he listened with such eager attention in his student days. Virchow is still here, active as ever, lecturing and demonstrating every day, with the same ease and accuracy, wasting no words, omitting nothing important, quiet, undemonstrative, precise, incisive as of old, with the same twinkle of the eye at every merry bon-mot, or, what occurs oftener, at every bit of satire. Advancing years have dealt very gently with him, as, except for a few gray hairs, there is no difference from fifteen years ago. He says there is a difference; that he is not so industrious as then; but the crowds of students and the heaps of material about flatly contradict him. Perhaps it is not right to say it, but I rather suspect that the lacking volume to the Geschwulst-lehre, and the lacking new edition of the Cellular-Pathologie, are due to the difficulty—it was Harvey who said it of himself in an apology for not at once receiving Asellius' views—of accepting newer doctrines at a later time of life. Inasmuch as I am not writing for posterity, I may not hesitate to say that I heard, not the professor himself, *Gott bewahr*, but a man high in the pathological department, say that Cohnheim's discovery was a *kinderspielerei!* This is dreadful gossip, and I would not mention it if it did not keep repeating itself like an echo round about. At our distance we can easily see that corpuscular migration was a most valuable discovery, if only, like its immediate predecessors, as a stepping-stone to something else; for it brought us back more peremptorily than anything before it, to look into the blood itself for the cause of the disease. But I was speaking of Prof. Virchow. What else could a student say, after the first salutation, than to observe that he had come back to the source of the waters to learn something more and something new? And to this came the quick reply, with a little touch of irony perhaps, "*Es giebt hier Nichts wie Pilse jetz!*" (there are nothing but germs here now). "It has been found out at last," he added, "that different germs can be colored different ways."

The regular didactic lecture to-day was upon osteomyelitis, and it is needless to say that the subject was handled with the easy grace of the master. There are about a hundred students upon the benches (the classes here are divided), and they show up a group about as motley as with us. Most are in strained attention, some are listless, some are restless. It is a great fault at all the lectures which I attended to-day that students came straggling in for half an hour after time. The lecture was abundantly illustrated with specimens, wet and dry, arranged upon tables in front, though but one or two were really picked up, talked about, and handed about the class. The discourse was just such a chapter as one might read in any good text-book, but it was very clearly and distinctly rendered, and was easily in the comprehension of every student in the room.

Osteo-myelitis gave opportunity, of course, for something about parasites, and I listened eagerly for what I knew must come in the section on etiology. In this regard there was something of a disappointment. The presence of germs was admitted, the existence of various kinds which are now being so attentively studied, but it was insisted upon, with more emphasis than seemed justifiable, that these germs may act, not only vitally, so to speak, but also chemically; that is, may evolve in their living processes a toxic substance which acts like a poison of chemical nature, and thus produces the malign effects attending sanies and ichor. This was the substance of what was said about germs in a very short time, considering the paramount importance

of etiology nowadays, while the bulk of the lecture was upon the pathological appearances of bone caries and necrosis.

Frerichs looks older than fifteen years ago; a most natural thing, indeed, but always an unwelcome thing to see in those whom we respect and esteem so much. If one would simply sit and listen with closed eyes, however, to his rich, deep, but distinct voice, as he sits upon the edge of the table, at the side of the bed, brought in before the class, he would not know that nearly a score of years had elapsed since he had heard the same words, so expressive of years of study and reflection.

Three cases came successively before the class—one of mastoid abscess, one of typhlitis, and one of cystopyelitis—a pretty good assortment for a hap-hazard clinic, as it was with me. A student is called down at each case, according to the German method, and the professor mostly talks to him, rather than to the class. If he looks up at all from the patient before him, it is at the student only, in expectation of an answer to the question addressed to him.

The first case was a good opportunity for the exhibition of a thorough clinical acquaintance with the cerebral circulation, in connection with the study of venous thrombosis, and it flowed as easily and voluminously as the current of a mighty stream. The typhlitic case was typical, and the lines were nicely drawn about peritonitis circumscripta and diffusa, ex continuitate, contiguitate, and ex perforatione. But the chapter on etiology was not so full as that on symptomatology and treatment. It was the old citation of hardened feces, foreign bodies, constipation, and the like, without allusion to, or explanation of, the fact that most cases affect males, with whom constipation, etc., is more rare, and among tuberculous patients, in whom arrest of peristalsis and accumulation of specific toxic products are so wont to occur.

After the brief history of the third case had been read by the clinical assistant to the class, mentioning merely the localized pain, the fever, and a previous attack of gonorrhœa, and the flask of blood-colored urine, scant in quantity, rich in albumen, but devoid of casts, was shown, the professor looked up in his usual quiet way for a diagnosis. "Nephritis," said the student. "Nephritis is a big word," said the professor, "and covers a multitude of things." Hereupon followed a rapid exclusion of any form of nephritis, and an easy inferential diagnosis of urethritis, cystitis, and pyelitis in the simplest possible sequence. But with all this, the chapter on etiology was unsatisfactory again. It was the old story of inflammation from calculi (pyelitis calculosa, with an ore rotunda, hard to describe), from catheterization, gonorrhœa, etc., but not a word about specific germs of any form.

Truly, we may lament, as Darwin did, about his theory, in a later edition of one of his works, "that the honored chiefs of our science have not yet given in their adhesion to the later views,"

I have not dared, as yet, to ask any of the "honored chiefs" what they thought about the bacillus tuberculosis, but Dr. Juergens, Virchow's first assistant for now over eight years (he has a book in press, by the way, and is about to describe a new disease, a new abdominal disease, so he told me to-day), shrugged his shoulders when I asked him about the bacillus tuberculosis, "We must wait awhile," he said. "I know that they are there, but I do not know that they are the cause of the disease." "Do you know Dr. Kock?" I ventured to inquire. "No, I have not seen him as yet, but I must look the subject up."

Nevertheless, the air rings with micrococci and bacilli about Berlin. It is something of a suppressed murmur as yet, and muttered mostly by the younger men, but it is gathering in force every day, and, so far as I can see, it threatens soon to play like a whirlwind with many cherished views.

And there is one man who does know that the bacillus tuberculosis is a fixed fact in science, and who is able to convince any one that it, and it alone, is the cause of the disease. May I say that they only shrug their shoulders who have not had time, as yet, or inclination, "to work the subject up," that, as Mr. Huxley said of Darwin long ago, "those who disbelieve him have never read his works." But about them and him another day.

BERLIN, June 20, 1882.

REMINISCENCES OF EARLY MEDICAL TEACHING IN NEW ENGLAND.

To the Editor of THE MEDICAL NEWS.

DEAR SIR: Several years ago I had the honor of receiving, from a member of the family of the late Dr. Mifflin Wistar, an original letter of Dr. Waterhouse, addressed to Prof. Caspar Wistar, a copy of which is now printed below. It is interesting on account of its statements respecting the history of American medicine in Colonial times, and as a literary relic of a man who was in Boston almost as eminent as Dr. Wistar was in Philadelphia. Their early career was very nearly the same. Both studied medicine at Edinburgh and at Leyden, although not at the same time, for Waterhouse was eight years older than Wistar. He was born at Newport, R. I., in 1754, and, after holding the Chair of Theory and Practice of Medicine in Harvard University from 1783 to 1812, died in 1846, at the patriarchal age of ninety-two.

Wistar, as every Philadelphia physician knows, or ought to know, was born in 1761, and died in 1818, aged fifty-seven years. This letter was addressed to him when he was at the height of his fame, in 1808, the very year in which he was promoted from the Adjunct Professorship of Anatomy to the Chair of Anatomy in the University, an office which he brilliantly illustrated until his death. Even twenty years after this untimely event, the memory of his eloquent teaching and benignant character was still fresh and influential in the traditions of the school.

Yours, very truly, A. S.

3900 SPRUCE ST., PHILADELPHIA,
June 10, 1882.

CAMBRIDGE, Sept. 22, 1808.

DEAR SIR: Your inquiries respecting the history of anatomical instruction in New England led me to make a critical investigation of this matter.

The first anatomical lectures ever given in this region was in 1754, at Newport, Rhode Island, by Dr. William Hunter, a young Scotch physician. They were delivered gratuitously to the principal gentlemen of that Island, and were very well received. By what I can discover, they were old Dr. Monro's lectures, as far as regarded the order and the physiological and pathological remarks. Dr. Hunter's son is a gentleman of distinction in the line of the law at Newport. He offered to show me his father's lectures in MS. I have often heard my own father speak of Dr. Hunter's lectures with great satisfaction. These anatomical lectures procured the young Scotchman considerable reputation, so that in two years after, viz., 1756, he was appointed Surgeon to the Rhode Island Regiment, destined to operate in Canada against the French. Soon after, Dr. Hunter married into one of the most reputable and opulent families in the Island; had the most extensive practice, and was actually the first *man* who ever practised widwifery in that colony. This gentleman was the father of the beautiful Miss Hunter,

"*the fairest among the fair.*" Such a piece of anatomy and physiology mine eyes never beheld.

Dr. Wm. Hunter, beside a good medical education, possessed taste in the fine arts. He collected paintings, while his all-accomplished daughter celebrated his taste in music. When the British occupied Rhode Island, this gentleman gave strong evidence of his attachment to his countrymen, and was appointed physician to their military hospital, where he apparently caught a pestilential fever, which carried him off in a few days. I therefore consider Dr. William Hunter, of Newport, Rhode Island, the father of anatomical and surgical instruction in New England.

Perhaps it may be gratifying to your colleague, Dr. Woodhouse, to hear that in the year 1759 a short course of lectures and experiments in chemistry and electricity was given at Newport by my brother, Timothy Waterhouse, and by Solomon Southwick. They were given, not like Dr. Hunter's anatomy, publicly in the Courthouse, but privately to about a dozen persons. The experiments related chiefly to the docimastic art. Boerhaave was their fulcrum. They believed in the transmutation of metals, and wasted their time and money in the delirious pursuit of making gold. Prior to this period a general literature was diffused through Rhode Island by means of the public library founded by *Abraham Redwood*, a Friend, the William Logan of Rhode Island, and well known, I presume, to the venerable James Pemberton, whom I regret not seeing. The residence of Dean Berkeley and of Dr. Stiles gave, I apprehend, a cast of science to my native place prior to most other spots in New England.

It may possibly be equally gratifying to your other colleague, Dr. Barton, to learn that the first public lectures on *botany* and on *mineralogy* in New England were given at the Rhode Island College in the summer of 1786. Two years after, this course of lectures was given at the University of Cambridge by the same person, and has been continued by him in an humble style ever since. The printed sketch, or first outlines of them, you have already in your hands. Give my regards to Dr. Barton, and tell him that I regret that time was not allowed me to see more of him. My best regards to Dr. Woodhouse, who must not fail to let me see him when he again comes this way. I have forwarded his letter to Dr. Prince.

To be journeying a whole month without a single half hour of bad weather; to return in high health, and to find my family equally well; to learn upon inquiry that no inconvenience had occurred in my business, were events too agreeable almost to be expected; yet I enjoyed all this. In addition to it, I was able to look back on my excursion from home with entire satisfaction, and shall never recollect but with sentiments of affection, the cordial reception and marked attention which I have received from my brethren in Philadelphia, among whom I shall always remember Dr. Wistar with peculiar satisfaction.

The only take off to the pleasure of my journey from your city to this place, was the queer, the very queer, conduct of my companion. I remained a day extraordinary at Rhode Island for his gratification; I carried him in a chair to see the island; I endeavored to pay that sort of attention to him which I supposed would please any man who had eyes to see or heart to feel; but all my efforts at Newport to introduce him to the best and the most beautiful company were so ungraciously received that I gave it up in dispair. He took one way to Boston and *left* me to take another. He has just called on me with Dr. Spooner, and made a sort of apology. The man has shown his wisdom in not marrying. Mrs. Waterhouse joins me in respectful remembrance to Mrs. Wistar and sister, and would be very glad to see them, or any of their friends, at Cambridge. Compliments to Dr. Currie, Judge Smith, and son. I shall write to Dr. Seybert to thank him for his pains in showing me his interesting collection of minerals.

The day after I arrived we had an equinoctial gale, and last night we had ice; and I write this by a good fire. Tell Robert Proud, I very much regretted that I was hindered from visiting him, as well as from visiting the nestor of *our* society. I remain, with a high degree of esteem, Your friend,

BENJAMIN WATERHOUSE.

DR. CASPAR WISTAR,
Professor of Anatomy, etc. etc.,
Philadelphia.

RESULTS OF VACCINATION.

To the Editor of THE MEDICAL NEWS.

SIR: Having read the correspondence of several members of the profession in regard to some rather peculiar results of vaccination, I would say, in answer to the request, that my experience during the past winter has been quite similar to that reported from Illinois. I used ivory points, and quills with efficient results. The peculiar results of vaccination that I desire to report, are as follows:

CASE I.—Female, aged 14, well nourished, and of healthy parents, vaccinated January 2d; ten days from above date patient had a severe rigor, followed with pyrexia. Patient took to bed, where she remained four or five days, arm swollen to elbow, vesicle as large as a five-cent piece, vomiting, nausea, and a quite severe headache. At fourteenth day the swelling had extended to tips of fingers, and the arm was about thrice its normal dimensions; patient also suffered from "darting pains" in the arm. At sixteenth day crust had formed, which was now as large as a half-dollar silver coin, and surrounded by a dark-red areola outside of which numerous little vesicles made their appearance, which in time became pustules, and again the site of small crustations. When the large crust came away it left a deep ulcer, which healed slowly under carbolized cosmoline. The length of time from vaccination to time of perfect recovery was about twenty-two days.

CASE II.—Female, aged 22, single, well developed, menstruation regular, vaccinated December 28, 1881. Eighth day from time of vaccination patient had a chill followed by fever, and intense swelling of arm and forearm, vomiting, nausea, very foul breath, and severe headache; patient took to bed, where she remained four or five days, when the crust had formed which, in this case, was about the size of a two-cent copper coin. As the crust came away a large deep ulcer remained, which healed readily under a bandage.

CASE III.—Sister to Case I., aged 7, healthy, vaccinated January 2; about seventh day from time of vaccination, quite severe stomach trouble, with rise in temperature, was manifested, which continued for about three days, and at the same time the vaccination passed through its regular course. The peculiarity in this case was that about three weeks after the subsidence of all symptoms of vaccination an eruption, very similar to rubeola, made its appearance on the trunk and lower extremities; no itching, no other symptoms of measles or scarlatina; and after a duration of three days passed away without treatment. Whether this eruption bore any relation to the vaccination, I am unable to say.

I have never before, nor since, witnessed results of vaccination similar to those above related.

Respectfully yours,
J. A. WESSINGER, M.D.

HOWELL, MICH., July 8, 1882.

NEW INVENTIONS.

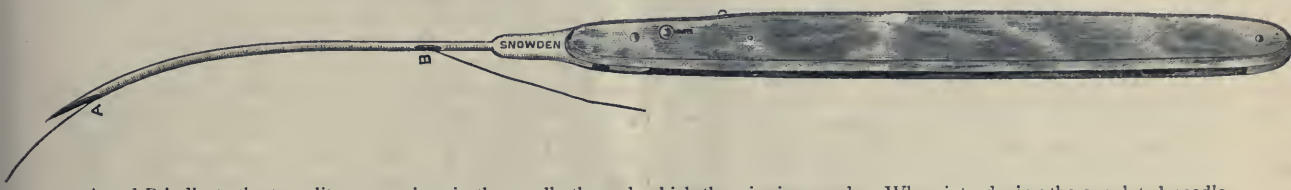
DESCRIPTION OF A CANULATED NEEDLE FOR INTRODUCING WIRE SUTURES IN SURGICAL OPERATIONS.

BY GEORGE McCLELLAN, M. D.,
OF PHILADELPHIA.

THE annoyance caused by the wire suture catching in the tissues on account of the doubling and twisting necessary to retain it in the eye of the ordinary needle is often very great, and the excessive oozing caused by the procedure most injurious.

In order to overcome this difficulty I had a little instrument constructed for me by Mr. Snowden, surgical cutler, No. 7 South 11th Street, which I have been constantly employing for several months in all operations where the approximation of the edges of the wounds required the introduction of wire sutures.

It consists of a long slender canulated needle, having a slit at the point, and another at the shoulder, where it joins the handle.



A and B indicate the two slits or openings in the needle through which the wire is passed. When introducing the canulated needle, the wire is of course either retracted or withdrawn, but as soon as the point A issues at the desired place the wire can be pushed forward, seized, and the needle withdrawn.

Although the idea of such a needle was entirely new to me when I first had it constructed, I have since learned that it was suggested and used by several surgeons many years ago. Dr. W. L. Atlee used a needle on this principle in his operations for ovariotomy, and Dr. Paul B. Goddard had needles of various sizes and forms for the purpose of passing wire sutures; but neither of these surgeons appear to have encouraged their general use.

The ordinary forms of needle, including the "screw-hole," and the "gutter-eyed," as well as the more recent suggestion of Dr. Morgan, of Baltimore, all require considerable time in their manipulation, and in many instances must be grasped by a holder that they may be properly introduced. In all of them the wire is apt to become caught in the tissues, or dislodged from the eye or stylet unless great care is taken to prevent it. The advantages of a canulated needle, such as is shown in the accompanying figure, will be apparent at a glance. The simple direct puncture of the needle will be found to occasion very little oozing, and as the handle offers firm support in the hand of the operator, great accuracy in the introduction of the sutures and complete exactness in the apposition of the parts are attained, the needle being made to transfix both margins of the wound at the same time, and the wire, when passed through taking its place.

The tearing of the knotted wire about the eye of a needle often causes a laceration instead of a puncture, and in some regions, as in the perineum or vagina, this minute rent is very apt to tear further when the sutures are tightened. The wire should always be carefully straightened by running it over the edge of the thumb nail to avoid any kinks which might interfere with its passage through the canulated needle. With this precaution it may then be introduced with much greater rapidity and precision than in any other way.

I have also found that this little instrument is very useful in taking the place of a tenaculum or artery forceps, either of which often loosen or tear away the ligature when they are being removed. I simply pass the needle through a bleeding point, then just forward the wire and withdraw the needle, leaving the wire so that it can be doubled into a loop, traction upon which will enable an assistant to throw a ligature completely round the vessel or bleeding point, as readily as a tenaculum, with this advantage, that as soon as the vessel is secured the wire may be cut, thereby avoiding the danger of displacing the ligature. This form of needle may also be used for the purpose of exploring. Upon introducing the point into a part where blood, serum, or pus is suspected to have accumulated, the fluid, if any exist, will pass through the needle and appear at the slit near the shoulder.

Objection may be raised to this form of needle on the score of the possibility of its conveying septic matter, but the same fault may be found with the hypodermic syringe, and it can readily be remedied by always retaining a piece of wire within the canulated needle when out of use and never forgetting to dip it in carbolized oil, both before and after it has been employed.

I need hardly say that the needle can readily be made straight or curved, as may be desired, but the form shown in the accompanying figure, which is designed for the pocket-case, will, I think, answer most purposes.

NEWS ITEMS.

LOUISVILLE.

(*From our Special Correspondent.*)

THE UNIVERSITY OF LOUISVILLE.—The Board of Trustees of the University of Louisville has elected Dr. John A. Octerlony to the Chair of Materia Medica, Therapeutics, and Clinical Medicine in the medical department of the University. Dr. L. S. McMurtry has been elected Demonstrator of Anatomy in the same institution.

THE NEW YORK CODE.—The action of the American Medical Association and other representative societies in relation to the "new departure" in New York, meets with universal approval throughout this State.

BALTIMORE.

(*From our Special Correspondent.*)

THE FACULTY OF THE BALTIMORE COLLEGE OF DENTAL SURGERY.—The vacancy caused by the withdrawal of Dr. James H. Harris from the Faculty of the Baltimore College of Dental Surgery, has been filled by the appointment of Dr. M. Whilldin Foster. Dr. R. B. Winder has been elected Dean of the Faculty, succeeding Dr. F. J. S. Gorgas, resigned.

The Faculty has been increased by the election of Drs. O. J. Coskery, Clinical Professor of Oral Surgery; C. F. Bevau, Professor of Anatomy, and Richard Gundry, Professor of Materia Medica and Therapeutics.

The three last-named gentlemen are also members of the Faculty of the College of Physicians and Surgeons.

BALTIMORE MEDICAL COLLEGE. — Dr. Archibald Atkinson has been elected Professor of the Principles and Practice of Medicine in the Baltimore Medical College.

A NURSE DIRECTORY, organized under the direction of the Medical and Chirurgical Faculty of Maryland, has been established, under the management of a committee of the Faculty, under the immediate charge of Dr. Wm. F. Lockwood. It is meeting with very encouraging success.

VIENNA.

(From our Special Correspondent.)

PROPHYLAXIS OF BLENNORRHŒA NEONATORUM.—Dr. Felsenreich, First Assistant in Prof. C. v. Braun's clinic, related at the last meeting of the Imperial and Royal Society of Physicians his experience in the prophylaxis of blennorrhœa neonatorum. Of five hundred trial-children, only two were sent into the Foundling Hospital with a light form of blennorrhœa. The results of his own experiments, and those of Dr. Borysikiewicz, Privat Docent, had created such confidence in Credé's prophylactic treatment that both Carl and Gustav Braun recognized it as routine treatment for every child born in their respective wards. In the time from March 1, 1881, to April 1, 1882, three thousand children were treated after Credé's method, and fifty-eight were sent to the Foundling Hospital with "sick eyes," 1.93 per cent., while a large number of children, treated according to an earlier method, simultaneously, gave a percentage of 4.34 of "sick-eyed" children. According to the view of Dr. Felsenreich, some special person must be entrusted with this duty, so that the midwife may have nothing whatever to do with the eyes of the new-born infant. He is of the opinion that the bathing-water is not instrumental in the communication either of catarrhal or blennorrhœal inflammations. Hausmann's and Olhausen's prophylactic treatment, *i. e.*, washing away the *materies morbi*, the vaginal secretions, from the eyelids and eyelashes with a solution of carbolic acid in water, he rejected totally, as being entirely inapplicable with midwives, who were sure to be careless in its administration. Credé's two methods: (1) washing out of the maternal genitals to prevent contact of the secretion with the conjunctiva, and (2) the introduction into the conjunctival sac of a corrosive fluid, such as a 2 per cent. argent. nitricum, so as to destroy the poisonous principle, are the methods now in vogue in these two clinics.

Hofrath Arlt, presiding officer, alluded to the difficulties, in the first days, of differentiating between catarrh and blennorrhœa. These difficulties totally invalidated the results of Dr. Königstein, undertaken in Prof. Spaeth's wards. The incubative stage of blennorrhœa is at least eight days; he was pleased that it was generally recognized that one had to contend with an infectious disease.

OBSTETRICAL NOTES: DILACERATION OF THE UMBILICAL CORD.—A strong woman gave birth to a child, while crossing the tracks of a tramway; the child fell upon the street-sand and the umbilical cord was torn in two. The child weighed 3200 grm., is perfectly healthy, and shows no sign of any contusion. The tear in the cord is about 10 cm. removed from the umbilical ring. This, however, is not the usual locality for dilaceration, in an upright or elevated position, to occur; for in this position rending generally brings with it a piece of the abdominal skin of the child or of the placenta, and tears it in its course, so that the division occurs 2–3 cm. removed from the umbilical ring. This matter is of great importance in a medico-legal aspect, where there is a suspicion that the mother herself has torn the cord in two, and then has laid the child aside. This suspicion can always be entertained when the remnant of the umbilical cord is long enough to admit of being grasped and torn. That avulsion of the umbilical cord generally is possible, the researches of Prof. Spaeth have abundantly proved. An average resistance of 5½ kilos., with fresh umbilical cords, has been determined by this investigator. The weight of a new-born child, 3 kilos., falling through the air, can readily overcome this resistance. Although in births in upright positions, not all umbilical cords are torn in two, yet the dilaceration is favored by a stretched course of the vessels, and by an absolute shortness of the umbilical cord. Avulsions of relatively short umbilical cords, that is, when the cords are wrapped around the necks or other portions of the bodies of children, occur very seldom during the act of birth.

A pertinent question is, can the life of the child be threatened by the indirect danger of hemorrhage? This danger only exists with feeble, asphyxiated children, and then only when the child is still in the maternal body. With strong children, however, who cry lustily, and breathe freely, it is possible to cut or tear in two the umbilical cord immediately after birth, and allow the child to lie without tying the cord; at highest estimate a coffee-spoonful of blood will escape. The vessels of the umbilical cord contract at once; their occlusion is favored by the circular fibres of the intima, and hemorrhage is arrested. On this account the verdict upon dead foundlings, by country physicians, "death in consequence of hemorrhage from the umbilical cord," is always to be regarded with a certain amount of suspicion and distrust.

THE LEWIS COUNTY (NEW YORK) MEDICAL SOCIETY AND THE NEW YORK CODE.—At the Annual Meeting of the Lewis County Medical Society the following resolutions were unanimously adopted:

Resolved, That the delegate from this Society to the New York State Medical Society is hereby instructed to use all honorable means in his power to have the New Code adopted at the last meeting of the State Society repealed. And, further, that he shall endeavor to have a special committee appointed to confer with the leading physicians in every part of the State as to their views regarding any changes desirable to be made in the by-laws and Code of Medical Ethics.

Resolved, That the above be published in the MEDICAL NEWS.

HEALTH IN MICHIGAN.—Reports to the State Board of Health for the week ending July 1, 1882, indicate that measles, typho-malarial fever, inflammation of the bowels, intermittent fever, whooping-cough, and puerperal fever, have decreased in area of prevalence. There was no marked increase in any disease reported. Including reports by regular observers, and by others, small-pox was reported present during the week ending July 1, and since, at four places, as follows: at Detroit and Grand Rapids; at Kalamazoo (one case, convalescent), July 3; at Flint (many cases), July 5.

LIGATURE OF THE INNOMINATE ARTERY.—On Friday, June 9th, Mr. WILLIAM THOMSON, at the Richmond Surgical Hospital, Ireland, tied the innominate artery in a man, aged 45 years old, who was suffering from a large aneurism, involving the second and third parts of the subclavian artery, and three and a half inches in diameter. An ox-aorta ligature, one-sixth of an inch in diameter, was employed, and was passed round the innominate artery by means of the instrument specially devised by Mr. Barwell for the purpose. On

the third day the tumor felt firm, and was already diminished in size; the wound remained aseptic, only a small quantity of serum oozing from the drainage tube. On the thirteenth day, the pain, from which the patient had suffered much before operation, had completely disappeared, and sensation was returning in the right arm, which had been paralyzed for several months by the pressure of the aneurism on the brachial plexus. The tumor is smaller and absolutely still, and the wound had entirely healed, except at one point, kept open by a few threads of catgut. The pulse is 98, and the temperature normal.

The result of this operation is of considerable interest, on account of its gravity and rarity. Fifteen cases of the operation are on record, of which only one, that of Smyth, of New Orleans, recovered. In this case there was severe secondary hemorrhage, and it became necessary to ligature the vertebral and internal mammary arteries.

Successor to Prof. von Bruns.—For the chair left vacant by the death of Prof. von Bruns, the Tübingen Faculty has sent in its list of recommendations, placing Prof. Bergmann, of Würzburg, first; Profs. Socin, Maas, and Schede, second; and Prof. Bruns, Jr., third.

Appointments.—Dr. Herman Knapp has been appointed to the Chair of Ophthalmology, and Dr. Newton M. Shaffer to that of Orthopedic Surgery, in the Medical Department of the University of the City of New York. Dr. Stephen Smith has been transferred to the Professorship of Clinical Surgery.

Assault on an Insane Hospital Superintendent.—Dr. Orange, the Superintendent of the Broadmoor Asylum, England, was assaulted by Rev. H. J. Dodwell, an insane patient. Dr. Orange was struck on the head with a stone slung in a handkerchief, but was only slightly injured as he was able to sieze his assailant and defend himself until aid came.—*Med. Times and Gaz.*, June 17, 1882.

M. Pasteur.—The Council of the Society of Arts of Great Britain have awarded the Albert Medal of the Society for the present year to M. Pasteur, Member of the Institute of France, for "his researches in connection with fermentation, the preservation of wines, and the propagation of zymotic diseases in silkworms and domestic animals, whereby the arts of wine making, silk production, and agriculture have been greatly benefited."

The President of the Royal Academy of Belgium has been invited by M. J. B. Dumas, Perpetual Secretary to the French Academy of Sciences, to join in the subscription organized by the members of various French learned bodies for a medal to be presented to M. Pasteur for his scientific discoveries.—*British Med. Journal*, June 24, 1882.

Prof. Nothnagel, of Jena, has been selected to fill the chair of Clinical Medicine and of Special Medical Pathology and Therapeutics at Vienna, made vacant by the death of Duchek.

Prof. Carl Schroeder, the Director of the Gynecological Clinic of Berlin, has been decorated by the King of Prussia, with the Cross of the third class of the Order of the Red Eagle.

Dr. Dujardin-Beaumetz has received the Chateauvillard Prize of 1500 francs for his "*Leçons de Clinique Therapeutique.*"

The Broca Subscription.—The sum subscribed to defray the expenses of a monument in honor of the late Paul Broca amounts to 22,449 francs.

Guiteaumania.—*The British Medical Journal* for June 24th contains a well-written editorial on Guiteau's insanity, from which we make the following extracts:

"Was there ever," asked Dr. William A. Hammond when recently addressing the New York Medico-Legal Society on the case of Guiteau, "was there ever a man whose whole career, from childhood to the present day, has afforded a more striking example of that form of mental derangement called reasoning mania?" and seeing that what Dr. Hammond calls reasoning mania is synonymous with what he might as correctly call arrant roguery, the answer which he anticipates and desires may be given to this question. That Guiteau has been an arrant rogue, or, according to this new self-contradictory euphemism, a reasoning maniac, from his youth up until now, will scarcely be denied by anyone who has glanced at the reports of his trial; and we fail, therefore, to perceive the necessity for the elaborate proof which Dr. Hammond adduces in support of this self-evident proposition. It may be well to examine Dr. Hammond's position, and inquire what justification he has for applying the term lunatic to the assassin of President Garfield.

We do not now enter upon the general question whether it is expedient to divide lunatics into two classes, one of which shall be amenable to penal discipline, and the other only to medical treatment, further than to say that to do so would be to run counter to all advances hitherto made in the medical jurisprudence of insanity, and to create difficulties greater than have yet been experienced in the administration of the law. Efforts have heretofore been directed to reconcile the legal definition of insanity with the scientific description of it; and the attempt to force these two asunder, to limit the former to a small group of idiots and raving madmen, and to extend the latter so that it shall include half the human race, can only end in inextricable confusion,

Now, what do all these evidences of insanity brought forward by Dr. Hammond amount to but the description of the career of an unscrupulous and sanctimonious adventurer? Are there not thousands of men in the United States and every civilized country whose lives, if carefully reviewed, would present as many mad points as that of Guiteau—mad points which make a specious show when brought together, but which are really of no account when scattered over long tracts of commonplace rational conduct? . . . Taking these proofs individually, there is not one of them that bears the stamp of madness; and, taking them collectively, they are incompatible with any theory of mental aberration. Insanity is often regarded as a lawless condition, of which anything and nothing may be equally predicated; for it seems to those who look upon it carelessly from afar to be a wild storm of thought, blowing where it listeth, and without centre or limitations. To those, however, who have studied it more closely and discerningly, there are revealed order in its ravages, and system in its cycles; and to them it becomes possible to say, in many instances, what course it will pursue, what features are characteristic of it, and what conjunctions are never witnessed in it. And skilled students of mental meteorology of this kind, who are free from personal bias and the thraldom of premature judgments in print, will certainly say that Guiteau's case, as described by Dr. Hammond, is not classifiable under any variety of insanity with which they are acquainted.

But Dr. Hammond's description of reasoning mania is not in conformity with medico-psychological experi-

ence on this side of the Atlantic. Such lunatics are not to be met with in asylums. They are a new discovery in the fauna of insanity in the United States; and we would suggest to Dr. Hammond that, as Guiteau is the most striking specimen of this kind of lunatic that has yet been discovered, he should substitute for the cumbersome and inconsistent name that he has adopted, the unmistakable designation of "Guiteaumania." We should then, with greater facility, be able to discuss with him the symptoms and medico-legal relations of this unique variety of mental alienation, as he would call it, or of moral turpitude, as we should prefer to designate it.

We have said that Guiteaumania is not recognized in Europe as a form of mental disease either involving irresponsibility or calling for curtailment of liberty or medical treatment. It may be admitted at once that Guiteau had an ill-balanced and depraved mind; but to this admission it must be added that he was not, in these respects, a whit worse off than three-fourths of the inmates of our convict prisons, who are notably infirm of purpose and inconsequential in thought, but who are nevertheless treated like accountable beings. The shrewdness and perspicacity which Guiteau displayed in his running accompaniment of interruptions throughout his trial, render it impossible to argue that his intellect is in any degree enfeebled. His power of apprehension and of forseeing the drift of any questions asked, was incontestably proved on innumerable occasions to be unusually acute; his memory was repeatedly shown to be tenacious and serviceable; and his judgment, when applied to the actions and motives of others, was often exhibited in a favorable light as regards its clearness and penetration. The anxiety which Guiteau displayed about his personal safety, and the precautions he took to secure it, are sufficient evidence that he is amenable to ordinary human motives; and the self-restraint which he more than once exercised when it suited his purpose to do so, betokened the possession of ample volitional power at his command. His crime was not a reckless and motiveless one, nor can it be said that it was prompted by any delusive belief. Of course, but few crimes have one sufficient motive; most are the resultants of several convergent mental forces: and so in Guiteau's case it may be impossible to put one's finger on any single spring of action, and say this impelled the fatal bullet; but still it may be safely averred that, in his itch for notoriety, his disappointments, his miscalculations, there is enough to account for his guilty performance without resorting to any theory of insanity in explanation of it.

NOTES AND QUERIES.

TREATMENT OF FRACTURE OF THE HUMERUS.

To the Editor of THE MEDICAL NEWS.

Dear Sir: In connection with the hypothetical case of fracture of the humerus, presented to the section on surgery of the American Medical Association (see THE MEDICAL NEWS, July 1, 1882, p. 24), by Dr. McLean and condemned by Dr. Sayre, allow me to report a case recently treated by myself with the best result attainable.

A boy aged ten years, healthy, broke the humerus by being thrown from a horse; the fracture was oblique and in the middle third near the junction with the upper third; the end of the bone was much displaced, with no, or but little, laceration of soft parts; having brought the parts into apposition, I applied a roller from phalanges to axilla; on this internally from axilla to condyle of humerus, I placed a double thickness of pasteboard (bonnet board), the same externally from acromion to condyle; this allowed free passive motion; the hand was placed in sling and arm fastened to the body by several turns of roller, passive motion, however, was used every two or three days. At the end of two weeks the splints were removed, the arm being kept in sling some time longer. The best result was attained at the least possible inconvenience to the patient, and I will pursue the same treatment of fracture of the middle third of the humerus in the future.

Very respectfully, etc.,

J. M. BERRIEN ROGERS, M.D.

CLARKSVILLE, IND., July 6, 1882.

THE POISONOUS ACTION OF SALIVA.

To the Editor of THE MEDICAL NEWS.

Dear Sir: In your issue of July 8, there is a communication from Dr. Geo. M. Sternberg respecting some remarks made by Dr. Formad at a meeting of the West Philadelphia Medical Society, published in the MEDICAL NEWS of May 27 (p. 585). Dr. Formad, in the course of those remarks, has also made a mistake with reference to the results obtained by me.

He says: "A student of mine, Mr. Claxton, made a number of experiments, and could not corroborate some of Dr. Sternberg's conclusions. *On the contrary, he found that any saliva, even that of animals, promptly killed those experimented upon.*"

Why Dr. Formad made this assertion, I cannot imagine, since the only salivas used by me were human and that of dogs dead of hydrophobia, and the latter only collaterally, as my investigations were wholly with respect to the former, *i. e.*, human saliva.

In order that Dr. Sternberg may see my views on this subject, I would refer him to my article in the *Philadelphia Medical Times*, of June 17, 1882, p. 627 *et seq.* He will find, I am gratified to state, that the results I have obtained accord, for the most part, with his.

Respectfully yours,

CHARLES CLAXTON, M.D.

ATLANTIC CITY, N. J., July 9, 1882.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT, U. S. ARMY, FROM JUNE 27 TO JULY 10, 1882.

By direction of the Secretary of War, the Medical Examining Board convened in New York City by S. O. No. 223, October 30, 1877, from A. G. O., is dissolved, to take effect June 30, 1882, and the following-named officers, now members of the Board, will report by letter to the Surgeon-General:

Major JOSEPH B. BROWN, Surgeon.
Major JOSEPH H. BILL, Surgeon.
Major CHARLES H. ALDEN, Surgeon.

—*S. O. 147, A. G. O., June 26, 1882.*

GARDNER, E. F. *Captain and Assistant Surgeon.*—Relieved from duty at Vancouver Barracks, Washington Territory, and assigned to duty as Post Surgeon at Fort Cœur d'Alene, Idaho.—*S. O. 83, Department of the Columbia, June 19, 1882.*

O'DONNOGHUE, F., *Captain and Medical Storekeeper.*—Died at New York City, June 29, 1882.

HEAD, JOHN F., *Lieutenant-Colonel and Surgeon.*—Granted leave of absence for fifteen days.—*S. O. 153, A. G. O., July 3, 1882.*

FORWOOD, WM. H., *Major and Surgeon.*—To report in person to the Lieutenant-General at Fort Washakie, Wyo., on or about July 23, 1882, for duty as Surgeon and Naturalist on a tour of inspection aud exploration to be made by the Secretary of War and the Lieutenant-General.—*S. O. 70, Department of the Platte, July 6, 1882.*

BARNETT, RICHARDS, *Captain and Assistant Surgeon.*—To accompany the Brigadier-General commanding on his journey to Forts Bridger, Wyo., and Thornburgh, Utah.—*S. O. 70, Department of the Platte, July 6, 1882.*

Under the provisions of Section 1 of the Act of Congress, approved June 30, 1882, the following-named officers are, by operation of law, this day retired from active service, viz.:

Brigadier-General JOSEPH K. BARNES, Surgeon-General.
Colonel JOHN. M. CUYLER, Surgeon.
Colonel WILLIAM S. KING, Surgeon.
Lieutenant-Colonel JAMES SIMONS, Surgeon.

—*S. O. 151, A. G. O., June 30, 1882.*

THE MEDICAL NEWS *will be pleased to receive early intelligence of local events of general medical interest, or which it is desirable to bring to the notice of the profession.*

Local papers containing reports or news items should be marked.

Letters, whether written for publication or private information, must be authenticated by the names and addresses of their writers—of course not necessarily for publication.

All communications relating to the editorial department of the NEWS *should be addressed to No. 1004 Walnut Street, Philadelphia.*

THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. XLI. SATURDAY, JULY 22, 1882. No. 4.

ORIGINAL LECTURES.

CLINICAL REMARKS ON SCARLET FEVER.

Delivered in the New York Foundling Asylum, April 22, 1882,

BY PROF. J. LEWIS SMITH, M.D.

(*Concluded from page 59.*)

IT will be necessary in the brief time allowed for a clinical lecture to pass over or only briefly allude to some subjects of interest relating to scarlet fever. One is the incubative period, which varies from a few hours to nearly a week, being, like that of diphtheria, different in different cases. Rarely there is apparently no incubation. Dr. D. W. Richardson (Clinical Essays, 1861, vol. i. p. 94) states his own experience. He had applied his ear to the chest of a patient suffering from scarlet fever, and was conscious of a peculiar odor emitted by the patient. He was immediately nauseated and chilly, and from that moment he dated the beginning of an attack of scarlet fever.

In the Transactions of the Clinical Society, London, vol. xi., 1878, C. Murchison gives the statistics of seventy-five cases showing the incubative period; as follows:

In	4	cases	it was not more than	24	hours.
"	2	"	" "	30	"
"	3	"	" "	36	"
"	4	"	" "	40	"
"	1	"	" "	41	"
"	4	"	" "	48	"
"	1	"	" "	54	"
"	1	"	" "	2½	days.
"	2	"	" "	3	"
"	1	"	" "	3½	"

In 31 other cases it was within 4 days, the time not being more accurately ascertained.

In	2	cases	the period did not exceed	4½	days.
"	17	"	" "	5	"
"	2	"	" "	6	"

Total number of cases 75.

In three cases Murchison believes that the time of infection was precisely fixed at 36 hours, 3 days, and 4½ days.

Passing over the fact that scarlatina is less contagious than most of the other eruptive fevers, probably from the fixity and feeble volatility of its specific principle, so that Dr. Billington (N. Y. *Medical Record*, March 23, 1878) found that in twenty-six families, in which ninety children were exposed to the malady, only forty-three, or about 50 per cent., contracted it; passing over the fact that its area of contagiousness is small, so that effectual quarantining in a domicile is easy if all intercourse with the infected room be prevented; passing over the fact that from unknown causes the type of scarlet fever varies in different seasons, varies beyond that of any other infectious malady except diphtheria, we come now to an interesting subject to which I wish to call your attention—one not so generally known as those to which I have alluded. The fact has long been known that after surgical operations, and even sometimes in surgical cases not requiring operative measures, a scarlatiniform efflorescence appears upon the surface of the whole, or nearly the whole, body, and remains for several days. Cases observed have been adults as well as children. Sir James Paget and other distinguished London surgeons regard this disease as true scarlet fever in most instances, and they designate it surgical scarlatina. They believe that there has been a previous exposure to the scarlatinous poison, and that the surgical ailment or operation furnishes favorable conditions for the occurrence of scarlet fever; so that the previous reception into the system of the scarlatinous poison, which probably would have been without result in ordinary health, causes an outbreak of this malady. The following were cases of the kind alluded to, published in *Guy's Hospital Reports* for 1879, by H. G. House, M. S.:

On March 15, 1878, Mr. Jacobson performed osteotomy in Guy's Hospital upon a child suffering from extreme rachitis. The operation was followed by a moderate febrile movement (100° to 101°), and after three days by the appearance of a roseoloid rash with sore throat and the strawberry tongue. The operation was made under carbolic acid spray, with all the details of antiseptic treatment. The rash soon faded, the temperature fell, and the child temporarily separated from the other patients, from the suspicion that her disease was scarlet fever, was brought back to the ward. The skin desquamated, and on April 1st abundant albumen was found in her urine. The result was favorable. Three months previously the same operation had been performed on the other leg with no unfavorable symptoms.

On April 5, twenty-one days after the performance of this operation, a lipoma was removed from another patient, aged 21 years. The following day the temperature rose to 101°, and remained at that till April 8, when it suddenly increased to 103.6°, and a rose-rash occurred over the body, with sore throat. On April 9, Mr. House excised the elbow-joint of a girl of 16 years, having "pulpy disease;" on the 10th her temperature began to increase, and on the 11th reached 105.8°. Toward evening a roseoloid eruption occurred over her body. On April 12, Mr. H. excised a fibroid bursa patellæ from a woman of 29 years. On the following day her temperature was 99°, but on the 14th it rose to 100°, and on the evening of the 15th she had rigors and headache. On April 16 her temperature was 102.5°, and a roseoloid eruption occurred over the face and chest. The surgeons now perceived that an epidemic of the so-called surgical scarlatina was occurring so as to justify the postponement of other operations.

In the same volume, Mr. James F. Goodhart gives the histories of nearly thirty cases of this disease occurring during a series of years in Guy's Hospital. The patients were chiefly children having the most diverse surgical ailments; among which may be mentioned hip disease with abscess, genu-valgum without operation, necrosis of femur, hydrocele with explorative operation, a scald, a sinus over the great trochanter, spinal disease with abscess. In cases operated on the intervals between the operations and the occurrence of the efflorescence varied from two days to more than two weeks. Mr. Goodhart, after a careful examination of the records of these cases, formed the opinion that the disease was for the most part true scarlet fever, especially as a considerable proportion of them occurred in groups, and there was a known exposure of some of the patients to children admitted with the sequelæ of scarlet fever.

In the *British Med. Journ.*, January, 1879, Mr. George May, Jr., reported a case of surgical efflorescence, which appears to have been true scarlet fever.

A child was operated on for the radical cure of hernia on December 4th. Towards the close of the same day he became restless, vomited, and on the day following his pulse had risen to 136. Forty-eight hours after the operation a rash appeared on the chest and arms, the abdomen became tense and painful, and on the following day he died.

Those who have reported cases of this form of efflorescence have for the most part neglected to state whether the patients had had scarlet fever previously; an important omission, since the differential diagnosis is so difficult between septic and scarlatinous efflorescence; but there can be little doubt that surgical maladies of a certain kind, especially traumatism, do produce a state of system which predisposes to scarlet fever; so that this class of patients are very liable to contract this disease when exposed to the scarlatinous poison; therefore a considerable proportion of the reported cases of surgical scarlatina were apparently genuine examples of this disease, but in, I think, at least an equal number the efflorescence was not scarlatinous, but septic. Moreover, when consultations were held opinions were very apt to differ, some believing the disease septicæmia, others scarlatina. In certain of the cases it is stated that the fauces presented their normal appearance. Now, faucial redness may or may not occur in septicæmia, but I do not recollect ever finding it absent in scarlet fever. A normal state of the fauces, therefore, in surgical cases attended by efflorescence, shows that the rash has a septic, and not scarlatinous, cause. Again, when the rash appears irregularly upon the surface, and fades away in two or three days with abatement of the fever, and the conditions of septic absorption are present, the efflorescence is probably septicæmic.

There can be little doubt that the rash was septic in the following cases: A child of five years (*British Med. Journ.*, February 15, 1879) had inflammation of the lymphatic glands in the groin, which suppurated. At the time when the abscess was fully developed, a rash appeared over the entire body paler than that of ordinary scarlet fever. It consisted of red points with pale spaces between them: temperature never above 99°, no sore-throat, nor desquamation of cuticle. Her sickness could not be traced to any exposure, and no child exposed to her contracted scarlatina. In the *British Med. Journal*, January 4, 1879, Mr. J. Braxton Hicks relates the case of his son, who, while attending school at Reading, was seized with a severe attack of pyrexia, accompanied on the second day by delirium and the occurrence of a rash like scarlet fever over the entire surface. He had no decided redness of the fauces, though they were perhaps slightly flushed. The right buttock was swollen from inflammation, and a large deep abscess formed near the tuberosity of the ischium. When the delirium abated the boy stated that he was standing the day before the fever began with his legs far apart, when a school-fellow stretched them farther, by suddenly pulling upon one of them. The rash, which was nearly universal, lasted three days, and disappeared without desquamation. No case of scarlet fever occurred in the school before or afterwards. In the same volume of the *British Med. Journ.*, Surgeon Frolliott, of the East India service, relates the case of a private, aged 23 years, and three years in India, who, when on duty in the Punjab, was severely injured by the explosion of an Afghan powder magazine. The accident occurred December 21, 1878. On December 25th a bright scarlet rash appeared upon the abdomen and spread over the entire body. On the following day the eruption was very vivid like a boiled lobster and lasted for five days. The temperature, which at the beginning had been 101°, abated to the normal after the rash appeared, no soreness of the throat nor redness of the buccal surfaces occurred, but the cuticle desquamated even from the palms of the hands and soles of the feet.

Scarlet fever is so rare in India that, after twelve years' service, Surgeon F. had not heard of one case among the resident Europeans or natives, and no case had occurred among the troops. We may, therefore, I think, safely conclude from the examination of published cases that certain forms of surgical disease, especially traumatism, do predispose to scarlet fever both in children and adults, so that if they happen to receive the contagium of this malady from some exposure to it, they are more likely to suffer from an outbreak of scarlatina than when in a previously healthy state. On the other hand, a sufficient number of cases in medical literature establish the fact that a scarlatiniform efflorescence of a septicæmic nature occasionally occurs in surgical patients sustaining no relationship with scarlet fever, and probably this form of efflorescence is as common as the scarlatinous in surgical diseases. These remarks are also applicable to obstetrical as well as surgical patients. Women after parturition appear to return to the state of childhood as regards liability to contract certain diseases, among which we may mention scarlet fever, so that it behooves the physician to be cautious, if he be engaged in midwifery practice while attending scarlet fever, that he do not communicate this disease to his lying-in patients. In the latter part of May, of the present year, a woman was admitted into the waiting-room connected with the maternity wards of the New York Infant Asylum from a family where scarlet fever was prevailing. On May 28th a primipara, who occupied a cot near her, was removed into the maternity wards and gave birth to a child. She was feverish from the time of her confinement, and on the third day the scarlatinous rash appeared over her entire body. On the sixth day it faded, and was followed by desquamation. She had some redness of the fauces. A similar case occurred recently in the New York Nursery and Child's Hospital. But a rash of a scarlatinous appearance occuring three or four days after parturition, while it may be due to scarlet fever, is more apt, I think, to have a septicæmic cause, resulting from decomposition of a blood-clot or a fragment of placenta. The following was a case in point, which came under my notice: Mrs. ——, aged 22 years, gave birth to her second child after normal labor on March 21, 1882. On March 23 she was restless, and complained of pain in both iliac regions; temperature in mouth 103⅓°; pulse 132; no cough. She was ordered quinia in 5 gr. doses, and salicylate of sodium in 15 gr. doses every four hours, with a pill containing one grain of opium and two of camphor between the doses. On March 25, a rash, like that of scarlet fever, appeared over her hands, forearms, hips, entire back, and the lower extremities as far as the knees; temperature 102°. March 27, morning temperature 101½°; evening temperature under tongue 104°; efflorescence over entire body except the face. The rash abated in a few days, the temperature fell, and convalescence seemed established. She had begun to sit in an easy chair, when, about two weeks after her confinement, on making an unusual exertion, she suddenly became faint, and expired before the physician could arrive. Possibly the efflorescence was due to the medicine, but it seems more probable that it was septic. That it was in all probability not scarlatinous, we may infer from the absence of faucial symptoms, and from the fact that the older child of the patient, aged two years, constantly exposed to her, did not contract scarlet fever.

Sometimes it is not difficult to make the differential diagnosis from the symptoms alone, between the rash of septic and that of scarlatinous blood poisoning, as

in the case of traumatism in India which I have related; in this case the fever abated while the rash was distinct and full, which is never the case with scarlet fever.

It will be necessary for want of time, after these general remarks, to postpone till next week the consideration of certain subjects which the case before us suggests, one of the most interesting of which is the complication of scarlet fever by diphtheria. These two maladies coexisted in the patient whose history you have heard, and whose viscera you have had an opportunity to inspect at the autopsy.

IS TUBERCULOSIS A PARASITIC DISEASE?

SECOND PAPER.

BY GEORGE M. STERNBERG, M.D.,
SURGEON, U. S. A.

DOUBTLESS many of those who have read Koch's report of his experimental inquiry, or the full abstracts of the same which have appeared in THE MEDICAL NEWS and the *American Journal of the Medical Sciences*, are of the opinion that the question which serves as a title for my paper, is already answered in the affirmative. Certainly the evidence as presented seems very convincing. But, as pointed out in my first paper, independent confirmation is especially necessary in this disease because tuberculosis, or at least a pseudo-tuberculosis not easily distinguished from the genuine, may be produced in rabbits and in Guinea-pigs by inoculating them with *non*-tubercular material; and because competent observers, Klebs, Toussaint, who have undertaken similar investigations, have announced the discovery of organisms in tubercular neoplasms which differ morphologically from the bacillus of Koch.

Negative evidence is rarely published, as it does not directly promote the advancement of science, and but little credit is to be gained by the investigator who has only negative results to record. They have, however, their value when the search has been thorough and conscientious, and it would be well if they were more generally published. The writer, although long since a convert to the germ-theory on theoretical grounds, has several times found himself compelled to report negative results where he had looked with considerable confidence for a discovery or for confirmation of a discovery already announced. At the present writing the same is true as regards the bacillus of tuberculosis, and although my observations are not sufficiently numerous to have great weight as opposed to the facts reported by Koch, they have a certain value, inasmuch as they show that *the bacillus is not present in all cases of tuberculosis;* and because they indicate a possibility of error on the part of observers not accustomed to the study of bacterial organisms and to the use of high powers, who may attempt to verify the discovery of Koch. This possibility arises from the fact that in preparations made strictly in accordance with Koch's method, the contour of the nuclei of cells often simulates so closely the appearance of bacilli contained in the cell, that it requires an experienced eye and careful focusing to detect the deception, and to the further fact that Koch's staining fluid is a medium in which bacteria may develop abundantly. This I discovered accidentally by leaving a thin section of lung (from a fragment preserved in alcohol) for several days in a shallow *covered* vessel immersed in the aniline blue solution prepared according to Koch's formula. Upon examining the section at the expiration of this time, I found that it was surrounded by a multitude of bacteria of various forms, including bacilli, that answered very well so far as form is concerned to the description given by Koch of his bacilli of tuberculosis, but which did not correspond with these in retaining their blue color when treated with visuvine. That these were developed in the staining fluid was proved by the fact that they were found in abundance upon the bottom of the porcelain dish in which this was contained, and that other sections from the same dish previously examined (after twenty-four hours immersion in the fluid) were quite free from bacteria. There is nothing surprising in the development of a variety of bacterial organisms in a slightly alkaline fluid containing fragments of animal tissue, and, *a priori*, it would hardly be expected that an alcoholic solution of methyline blue in the proportion of one-half per cent. would prevent such development. As, however, this development did not occur within twenty-four hours, the time given by Koch for the staining process, it may be that no mistakes are likely to arise from this source. On the other hand, the possibility of such a mistake should be borne in mind, especially in climates where, owing to a higher temperature, a more rapid development of bacteria would be likely to occur. My own accidental experiment was made at a time when the thermometer ranged constantly below 60° Fah., and has since been repeated with a like result.

Lest it may be thought from what I have already said, and from what follows, that I am attempting to bring discredit upon the *observations* of Koch, I desire to say that I have the greatest respect for the scientific acumen and technical skill which he has displayed in this and in previous investigations, and cannot doubt that he has seen what he describes, and has faithfully reported his observations. Believing this, I look for confirmation later when I obtain *the right kind of material;* for, from a review of the experimental evidence relating to tuberculosis, I am inclined to think that we will find eventually that there are two forms distinguished by the presence or absence of parasitic organisms, and by being infectious or non-infectious as the result of this circumstance.

The main object of, and it may be the only excuse for, the present paper, is to point out the necessity of exercising a spirit of scientific conservatism in judging of the value of the experimental evidence which is now being offered from many quarters in favor of the germ-theory of disease; and in view of the importance of the subject, I will perhaps be pardoned for making a slight discursion before recording the results of my observations as regards tuberculosis.

We are in even greater danger of being misled by the statements of those who claim to confirm, or by a second-hand report of experimental researches, than by the detailed report of an original investigation; for, in the latter case, the author generally gives a minute account of his methods and observations, while in the former we often have only the bare announcement without any data from which we can judge of the skill and care exercised by the one who confirms. And, in second-hand reports it unfortunately sometimes occurs that more is claimed than the original investigator felt justified in claiming, and where he had exercised a proper conservatism, his reporter may not only fail entirely in doing so, but may misquote the facts which he has recorded. Thus, in a recent address before the American Medical Association, I find the following statement:

"In 1879, Prof. Tommasi-Crudeli, of Rome, and Prof. Klebs discovered a parasite in the soil of malarious districts. The parasite was never found where malaria is unknown. The parasites were invariably found in the blood of persons suffering from malarial disease, but never in those free from such disease. Blood drawn from the veins of persons affected with malaria, and injected into the subcutaneous tissues of dogs, reproduces the disease in these animals."

All this seems very definite and conclusive, but in the original report of Klebs and Tommasi-Crudeli, I do not find a word about their having found the parasite in the blood of persons suffering from malarial disease, nor any record of experiments in which blood drawn from the veins of persons affected with malaria, and injected into the subcutaneous tissues of dogs, reproduced the disease in these animals. On the other hand, their experiments were made upon rabbits, and their announcement of the discovery of a *bacillus malariæ* rested entirely upon these experiments. It is true that Cuboni and Marchiafara subsequently announced the discovery of similar bacilli in the blood of man, but who has confirmed Cuboni and Marchiafara? The three cases of pernicious fever, in which the last-named gentleman found bacilli in the blood, the lymph, the spleen, and the marrow of the bones cannot count for much, in the absence of evidence showing that these could not have been developed *post-mortem*, for it must be borne in mind that in the latitude of Rome the development in the blood and tissues of a variety of bacterial organisms which habitually infest the alimentary canal, occurs very shortly after death, while in Catholic countries it is usually difficult to obtain an early post-mortem examination.

Malarial fevers prevail so extensively, and so many physicians are provided with microscopes, that it would seem as if the bacillus of Klebs and Tommasi-Crudeli should now be pretty well known to the profession, not only by report, but also by personal inspection, if it is truly the cause of malarial infection. As time passes this negative unrecorded evidence must acquire a constantly increasing value, for we can scarcely doubt that positive confirmatory results would be promptly heralded in the medical journals. But in addition to these inferred unrecorded results, we have the fact, in the case of malarial fever, that several other observers have described a different organism believed by them to bear the identical relation to the etiology of malarial fever ascribed by Klebs and Tommasi-Crudeli to their bacillus. The inference is evidently legitimate that these observers have not seen the bacillus in the course of their more or less extended investigations. Thus Laveran[1] describes an amœba-like organism, called by him *Oscillaria malariæ*, found only in the blood of malarial fever patients, and Richard,[2] in a recent communication to the French Academy, confirms this discovery.

It is not my object at present to weigh the evidence for or against either of these alleged discoveries, but simply to point out that each observer furnishes negative evidence which must be taken into account in considering the claims of the other. I may say, however, that in this case it is easier to believe that Klebs and others—myself among the number—have overlooked a parasite resembling so closely the leucocytes of healthy blood, as does that described by Laveran, than that Laveran, Roberts, Sternberg, and many others have overlooked an organism in the blood as easy of detection as the bacillus of Klebs and Tommasi should be from their description of it.

This argument does not apply with the same force to the bacillus of Koch, for according to his account a special method of staining is necessary in order to demonstrate it. We are not, therefore, justified in assuming the absence of this bacillus in the numerous preparations examined by Toussaint, for example, who has been for some time engaged in similar investigations. But what shall we say of the failure of Koch to find, or at least to describe, the micrococcus of Toussaint? The last-named observer has spent much time in the study of infectious diseases, and enjoys an excellent scientific reputation; it would, therefore, be difficult to say that the recorded observations of one or the other of these *savants* are worthy of the greater credence. All that we can say is, wait and see. Koch has fully described his method; there is no lack of observers competent to apply it, and material is abundant, so that the case of *bacillus tuberculosis* having been brought to trial in open court, we may confidently anticipate a verdict within a reasonable time. As already indicated, the object of the digression which I have permitted myself to make has been to impress upon the jury the importance of caution and scientific conservatism in weighing the evidence.

The material which I have thus far examined has come from the City Hospital, San Francisco, and has been furnished me by my friend, Prof. Hirschfelder, to whom I am also indebted for a supply of methyl blue and of visuvine. This material consists of samples of sputum from four consumptive patients in Dr. Hirschfelder's wards, obtained May 25, and two additional samples, obtained May 30; a fragment of lung, studded with tubercular nodules—

[1] Description of a new parasite found in the blood of patients attacked with malarial fever. Baillière and Fils, Paris, 1881.

[2] Comptes Rendu, Acad. des Sciences, xciv. p. 496.

cheesy—and including a portion of the walls of a cavity, obtained June 2, and a similar specimen from a second case, obtained June 19. In both of these specimens, and especially in the second, many of the cheesy masses had a dark color, due to the presence of innumerable amorphous granules (carbon?), which were opaque, and varied in size from that of the smallest micrococcus to angular or rounded fragments, one-fifth the diameter of a red blood-corpuscle. These specimens were obtained from the dead-house, and were not accompanied with histories of the cases, which were not from Dr. Hirschfelder's wards.

The samples of sputum obtained May 25, were examined the same day, with the following result: The examination was made with a Spencer's $\frac{1}{10}$-inch and a Zeiss' $\frac{1}{18}$-inch homogeneous immersion objective. The last-named objective, with a Tolles's amplifier in the tube of the microscope, and a medium ocular, gave me an amplification of 1500 diameters, with admirable definition. Illumination was effected by the use of a $\frac{1}{6}$-inch objective of Zeiss as an achromatic condenser, and the observations were mostly made by daylight.

Not having yet been able to procure a supply of visuvine, I could not apply Koch's test for the tubercular bacilli to the samples of sputum first examined; but as the specimens were stained with methyl blue, the bacilli should have been seen if present.

Results of Examination.—Specimen No. 1 contains numerous fatty pus-cells, much free granular matter, elastic fibres from disorganized lung tissue, a few red blood-corpuscles, rod-bacteria (*B. termo*), and micrococci in pairs, in chains, and in groups of four. No. 2 contains numerous pus-cells, the nuclei deeply stained with the methyl blue, and rod-bacteria solitary and in zoöglœa masses. No. 3 contains great numbers of micrococci in chains and in zoöglœa masses, and a few rod-bacteria. No. 4 contains fatty pus-cells, granular matter and numerous bacilli. This preliminary examination showed me that the sputa of consumptives contains in abundance the bacteria which constantly infect the healthy human mouth; but I was not able to recognize any form with which I was not already familiar, and the bacilli, bacteria, and micrococci referred to in my notes correspond morphologically with those shown in my photo-micrographs (Figs. 3, 4, and 6, plate xii.), which illustrate a paper read last summer before the American Association for Advancement of Science, and published in "Studies from the Biological Laboratory of Johns Hopkins University."[1]

Not having recognized Koch's bacillus among the familiar forms present in these samples of sputum, I requested Dr. Hirschfelder to obtain for me some additional samples, collected with special care, the patient being requested to discharge the material coughed up from the lungs into a clean, wide-mouthed bottle, endeavoring, as far as possible, to exclude the buccal secretions.

[1] A contribution to the study of the bacterial organisms commonly found upon exposed mucous surfaces and in the alimentary canal of healthy individuals. *L. c.*, vol. ii., No. 2, pp. 157–181.

It is evident that no amount of care can entirely prevent the inoculation of such a mass from the lungs by the bacterial organisms constantly present in the mouth, and but little time would be required for the multiplication of these to such an extent that the whole mass would be infected. This, and the further possibility that multiplication of the organisms contained in the specimen may occur in the staining fluid, should be borne in mind by those who examine sputa with a view to confirming Koch's discovery. The last-named source of error will, however, probably be avoided if Koch's method is strictly followed, and the thin layer of material attached to a cover-glass is exposed to a temperature of 120° to 130° C. for from two to ten minutes.

Examination of Sputa obtained May 30.—Sample No. 1 contains an abundance of pus-cells, a few red blood-corpuscles, epithelium from the mouth and numerous bacteria—micrococci and bacilli—like those found in normal saliva. No. 2 contains pus-cells, epithelium from the mouth, *Bacterium termo*, *Leptothrix buccalis*, micrococci in chains and zoöglœa masses, and bacilli, all similar to those heretofore described. Having obtained a supply of visuvine, staining by Koch's method was carefully and repeatedly tried, but without result, so far as the demonstration of his bacilli was concerned. I also made numerous experiments to ascertain whether any of the bacteria present in normal saliva would retain the blue color given by the methyl blue staining solution when treated with visuvine. The result was negative, but I must again warn the novice that there is liability to error in the application of this test, as bacilli and other forms of bacteria deeply stained by the visuvine *appear blue when a little out of focus*, and inexperience in observing these minute objects, a lively imagination, or *defective color sense*, might lead to mistake. Especially is this liable to occur if one not skilled in the use of the microscope attempts to follow the directions given by Koch with reference to illumination, in his work on "Traumatic Infectious Diseases." According to this method, stained bacteria are to be distinguished in the tissues by moving the achromatic condenser forward, past the point where the best definition is secured, so as to obtain a color-picture, the details of structure being obscured by this procedure, while colored objects are brought out in strong relief. Having already been more prolix than I at first intended, I will cut this paper short by saying that I have made numerous sections from the two specimens of tuberculous lungs obtained for me by Dr. Hirschfelder, that I have stained and mounted these according to Koch's directions, and have carefully examined them without having been able to find Koch's bacilli.

It is too soon to know the result of my inoculation experiments in rabbits, but these will be duly reported when completed, together with any additional observations which I may have the opportunity of making upon fresh material.

THE ACTION OF ERGOT IN A CASE OF DIABETES MELLITUS.

BY E. F. TIEDEMANN, M.D.,
OF O'FALLON, ILL.

SHORTLY after reading Prof. Da Costa's article in THE MEDICAL NEWS of January 7th, on the ergot treatment of diabetes insipidus, a case of diabetes mellitus came under my care; and then the thought entered my mind that ergot might be beneficial in the latter as well as in the former disease. The case was a desperate one, and I determined to make the experiment. The result was so surprisingly good that I am induced to think the case worthy of publication, and hope that ergot may be tried by others and its true value in diabetes mellitus established. I think it very probable that many cases of diabetes go on unrecognized for a long time, especially in cases occurring in the less intelligent classes; and for this reason I give the history of the case in detail.

On Jan. 31st, the wife of a farmer came to me to get medicine for her husband, J. S., a German, aged 54. From her statements I judged the case to be one of malarial intoxication, with gastric and hepatic disturbance, and prescribed accordingly.

On Feb. 1st, I was called to see him, as he had not improved. I found him in bed, pale and emaciated, and in a very weak condition. Though a man of the average intelligence of his class, he appeared dull, and I had considerable difficulty in obtaining his history. He has never been sick, with the exception of long-continued malarial fever in the years 1876–'78. Some few months ago he began to feel weak in his legs, was easily tired, had a ravenous appetite, but felt no pain or other inconvenience. Complains chiefly of great weakness, thirst, bad taste in his mouth, which is dry; his gums bleed easily. Tongue fissured; red and dry at the tip and edges, thickly covered with a yellowish fur posteriorly. His appetite is failing, he has eructations from his stomach, has vomited once to-day, for the first time, and has other dyspeptic symptoms; his bowels are constipated. Skin pale, cool, and dry; suffers much from itching, especially on his thighs, legs, and back; states that some slight bruises and scratches on his hand suppurated, extended considerably, and were a long time in healing. Has no pain in his back, nor tenderness on pressure there; states that his urine is "quite clear." Unfortunately, I forgot to ask him about the quantity of urine passed. A careful physical examination did not reveal disease anywhere. He did not volunteer any information, and his mental processes seemed to be carried on slowly. I was not at all satisfied as to the nature of his disease, producing so much exhaustion. His pulse was 76, moderately strong and regular.

Knowing that for some time he had been living on salt pork and other coarse food, I directed a light diet, with plenty of milk, and gave him a purgative and some bismuth and pepsin. I asked to be informed of his condition next day.

February 2.—His wife informed me in the morning that he had been constantly growing weaker since I saw him, and was worse in every respect. I put several questions to her, and, suspecting Bright's disease, asked how much water he passed. I was astonished to hear that he would rise as often as eight times a night to urinate; that an ordinary chamber-vessel not being large enough to hold the amount, he used a bucket holding two gallons, which was always about half full when emptied in the morning. When I asked her why she had not told me that before, she said she thought it was quite natural, as he drank water every time he rose, sometimes as much as a quart at a time. I asked her to measure carefully the amount he passed after she returned home, and to send me a specimen.

3d.—The amount of urine passed in twenty-one hours was *eighteen pints*, which would be over *twenty pints* in twenty-four hours. The urine is pale, of a greenish-yellow hue, semi-transparent. The specimen examined was taken from the whole amount passed, had a sp. gr. of 1034, and contained sugar in great amount. He was by this time in an alarmingly weak condition, brought about to some extent, no doubt, by the milk I had ordered. I put him immediately on half-drachm doses of fluid extract of ergot, with 15 grains salicylic acid, 20 grains sodium bicarbonate, and 10 minims of tr. opii, every four hours, and ordered the usual strict diet of proteids and fats.

4th.—The result of this treatment far exceeded my expectations. After he had taken four doses the amount of urine passed in twenty-four hours had fallen from *twenty* to *eight pints*. His thirst was lessened very much, he had risen but three times during the night to urinate, and felt stronger. I had feared that the specific gravity would rise very much, and was surprised to find that it was only 1036.

I now ascertained that he had been feeling weak since last fall, about September; that the thirst and feeling of weariness came on gradually and increased slowly. He stated that for some months he had been troubled with occasional numbness of his legs, and formication, a feeling, as he expressed it, of bugs and ants crawling on his legs. His sight had become much less acute, and his memory was failing. His gait was uncertain, especially in the dark or when rising from a lying position. There is no history of syphilis, traumatism, sudden nervous shock, or mental strain. He had never heard of such a disease, his parents lived to be quite old, and he has three brothers living older than himself. He had since early fall been drinking great quantities of cider, and when his excessive thirst commenced he probably drank still more. This habit is mentioned by Niemeyer as one of the alleged causes of diabetes mellitus.

The above-mentioned nervous phenomena were the only ones I could ascertain, and they led me to consider the disease in his case to be of nervous origin. He had never suffered from neuralgia or disturbed action of the heart; I could find no symptoms referable to vaso-motor disturbance such as flushes of heat or cold, cold feet, etc. The numbness, formication, and weary feeling, were equally severe on both sides of the body. He did not feel

any soreness in the muscles of his legs, but it was probably present and included in the word "weariness;" he is not very sensitive to pain.

5th.—Passed six pints of urine. Increased dose of ergot to one drachm every four hours. Rises but once during the night, and is gaining strength; sleeps well; bad taste in mouth disappearing; itching and formication much less.

7th.—Five and a half pints; patient is out of bed the greater part of the day.

8th.—Six pints, sp. gr. 1033. He had not eaten any sugar-producing food, with the exception of a very small piece of bread at his meals, and yet the sugar was present in almost the same proportion as the day after he ceased eating farinaceous food, showing that the disease had reached the stage when sugar is manufactured of animal food. The constipation is very obstinate, and is only overcome by large doses of salts.

12th.—Urine six pints, of sp. gr. 1032. Owing to continued constipation, I discontinued the opium and substituted potassium bromide with a few grains of potass. iodide.

15th.—Five and a half pints, sp. gr. 1038. Is feeling worse, complains of sweet taste in his mouth again, and has more thirst. Added opium again.

17th.—Four pints, sp. gr. 1034.

18th.—The daily amount of urine has fallen to *two pints*, sp. gr. 1039. I attributed this fall to the ergot, and directed all medicine stopped for twelve hours, and afterwards directed it to only be taken three times a day.

19th.—Three pints.

21st.—Five pints, sp. gr. 1033.

22d.—After eating farinaceous food, amount of urine rose to six pints, sp. gr. 1038. Patient found very soon that farinaceous food was harmful to him, increasing his thirst and producing a sweetish taste in his mouth.

March 2d.—Five pints, sp. gr. 1030. Patient walked to my office, a distance of two miles, with ease. General condition very much improved, appetite good, feels quite well, and is gaining flesh and strength. Reduced ergot to 30 minims thrice daily, and substituted ½ grain codeia for the opium; discontinued sodium salicylate entirely, but continued the alkali in 10 grain doses, three times a day.

6th.—Four pints, sp. gr. 1032. Directed cod-liver oil, and $\frac{1}{50}$ gr. phosphorus with each dose; increased codeia to gr. j, three times a day.

26th.—Five pints, sp. gr. 1027. Discontinued phosphorus.

April 6th.—Patient can work as well as formerly, and has no inconvenience. Sp. gr. varies from 1027 to 1030. Eats bread at every meal. Bowels regular, moving daily. His appetite continues very good. Takes the medicine but twice daily, and sometimes even goes without it for several days. On this account, increased ergot to 45 minims, and ordered in addition strychnia, iron, and quinia.

13th.—Patient continues well, doing hard work, as ploughing, hauling wood, etc., daily. The feeling of weakness in his legs is much diminished. The itching and the nervous symptoms are all gone. His sight has improved.

Of course, I do not claim that he is cured; I doubt if the disease is ever cured when it reaches the later stage. But to keep the disease in check, and prevent the excessive formation of sugar, ergot, I think, will in some cases be a useful means, especially when combined with opium, or, better, codeia.

What the lesion is in this case, I do not know; but it is probably one affecting, primarily or secondarily, a portion of the cerebellum and fourth ventricle. It is difficult to conceive how disease in the medulla oblongata can exist *primarily* and involve *only* the vaso-motor centre, or even only those portions that are known as the diabetic and the polyuric centres. And again it is supposed that the diabetic centre alone can be involved, or the polyuric alone. We meet diabetes mellitus without polyuria, diabetes insipidus without glycosuria, and finally, as in the foregoing case, diabetes mellitus with enormous polyuria, apparently a mixture of the two diseases, or rather a disease—whether actually situated in the floor of the fourth ventricle, or occupying some other spot connected with it—that affects both centres.

Da Costa thinks that the remedial action of ergot, in his cases of diabetes insipidus, consisted in capillary contraction in the nervous centres, meaning—as I take it—that portion of the fourth ventricle, irritation of which produces polyuria. It seems reasonable to expect that in cases of diabetes mellitus of nervous origin, excepting, of course, tumors or destructive changes, ergot might be successful in some cases of diabetes mellitus, as well as in diabetes insipidus. I think that my case is at least another confirmation of Da Costa's results.

The sudden fall from twenty to eight pints in twenty-four hours cannot be attributed to anything but the ergot and modified diet, and, in part, to the opium. The fall from eight to four, and even two, pints in two weeks, can, I think, be attributed *only* to the ergot, as he was under the modified diet all the time.

I do not think that the sodium salicylate produced any benefit, for when left off, after four weeks' use, improvement went on steadily, which was not the case when the opium or the ergot was withheld. The good results claimed by many observers to have followed the use of salicylic acid, suggest the thought to me that there may be a class of cases of diabetes mellitus in which a process of fermentation is going on excessively somewhere. The fact that other fermentation-checking drugs, as carbolic acid, creasote, iodine, quinia, lactic acid, and glycerine, have been highly recommended by many authorities, may lend some little support to this idea.

The opium was undoubtedly of great benefit, not only in allaying thirst, but in checking the production of sugar. This is shown by the observation that the specific gravity rose from 1032 to 1038 when the opium was withheld. He eat no more bread in these days than previously. The rise of the specific gravity to 1039, when the urine fell to two pints, can be explained by the great concentration.

Some of the nervous symptoms observed reminded

me of locomotor ataxia, with which, indeed, as regards progressiveness, diabetes has been compared. But the inco-ordination observed was probably due to trouble in the cerebellum, which is supposed to be a great factor in co-ordination, and *polyuria* is mentioned (Eckhard) as the result of injury to the cerebellum.

The effect of eating sugar in increasing thirst, and consequently augmenting the amount of urine, is of interest. It is observed in healthy persons eating large quantities of sugar. It shows that in diabetes mellitus there is, besides the frequent implication of the polyuric centre, another factor aiding to bring on polyuria. In the first case, the thirst is due to large losses of water; in the second, the sugar in the blood causes increased absorption of water from the tissues.

A rough estimate of the solids contained in the daily quantities of urine mentioned in the history of the case, and the comparison of these amounts with the quantities of urine in which they were contained, shows plainly *that the more urine was voided, the greater was the loss of solids*, consisting chiefly of sugar and urea. From this fact we can deduce a lesson of great practical value—*if we can lessen the polyuria, we can lessen the loss of sugar proportionately.* It also teaches us to restrict the amount of fluids consumed by the patient as much as possible. And I infer from this fact that the value of ergot in diabetes mellitus consists chiefly, if not entirely, in controlling the polyuria that accompanies it. In cases of diabetes mellitus without polyuria ergot is probably of no great benefit. And now arises the question, why is the amount of sugar voided in proportion to the amount of urine passed? There appears to be a mutual interaction, the sugar in the blood increases its watery portion, and the increased amount of the latter augments the discharge of sugar.

From the following table it is easily seen that the more urine was voided the greater was the loss of solids. The figures obtained to show the amount of solids represent only a very rough estimate, obtained by multiplying the last two figures of the specific gravity by 2.33, to get the amount of solids in 1000 parts of urine (Wickham Legg), and calculating from this the average in a pint, and the whole amount passed in the day. The increased production of urea should be remembered.

Date.	Amount.	Specific Gravity.	Average in pint.	Total amount in 24 hours.
Feb'ry 3,	20 pints.	1034.	600 grains.	12,000 grains.
" 4,	8 "	1036.	638 "	5,100 "
" 8,	6 "	1033.	585 "	3,500 "
" 12,	6 "	1032.	567 "	3,400 "
" 15,	5½ "	1038.	673 "	3,700 "
" 17,	4 "	1034.	600 "	2,400 "
" 18,	2 "	1039.	692 "	1,384 "
" 21,	5 "	1033.	585 "	2,925 "
March 2,	5 "	1030.	532 "	2,660 "
" 6,	4 "	1032.	567 "	2,268 "
" 26,	5 "	1027.	490 "	2,450 "

P. S.—*July 3.* The patient continues to do well; and has done very hard work during harvest, the weather being unusually hot and sultry.

MEDICAL PROGRESS.

COMPLETE INVERSION OF THE VAGINA.—A non-pregnant woman was recently admitted at the obstetric clinic of PROF. BRAUN, suffering from complete inversion of long standing. At first it was unaccompanied by pain, but later the painful sensations and interference with urination showed that there was also a prolapse of the bladder, proved by the backward and downward direction taken by the catheter; the rectum occupied its normal position. The uterus was not displaced, and the uterine sound could be introduced for a depth of about six inches; the cervix was elongated. Ordinarily such displacements of the female genital organs are due either to great weight of the uterus or relaxation or laceration of the perineum, or both combined; in this case the elongated cervix supplied the abnormal weight. Treatment may consist either in restitution and retention with pessaries, or may require an operation. In Prof. Braun's case a portion of the cervix and vaginal wall was excised and the edge brought together with stitches, and the rent in the perineum freshened and sewed up; the vagina was then tamponed with iodoform cotton.—*All. Wiener Med. Zeit.*, May 16, 1882.

THE ACTION OF CARBOLIC ACID ON FEVER PATIENTS.—DR. VAN OYE'S thesis, published at Paris in 1881, contains the following conclusions on this subject (*Journ. de Thérap.*, 10th February, 1882). Carbolic acid is a poison of the nervous system, and possesses in the highest degree the property of lowering the temperature of man and the higher animals. Doses of carbolic acid, without appreciable action on the normal temperature, are sufficient to lower the febrile temperature. This lowering is produced in febrile patients whether suffering from simple inflammation, or from infectious pyrexia. It commences very soon after the absorption of the medicine, and its extent varies, according to the dose, from one to three degrees, and its duration from one to three hours. Its probable cause is the loss of heat resulting from the cutaneous hyperæmia, and the more or less abundant sweats which coincide with its production. A rigor and all the phenomena of the febrile state supervene, when the antipyretic action of the preceding dose is exhausted. At the same time the temperature rises suddenly to its original level, and even above it. A new dose may interrupt this attack, and even prevent it if the medicine be administered in time. Doses which are sufficient to produce the entire useful antipyretic effect do not exercise any injurious toxic action on a fever patient. Fifty centigrammes administered by the rectum are sufficient in all cases at the outset. As a rule, doses of two grammes may be gradually reached. One gramme given at once has, in some patients of special susceptibility, been sufficient to produce a lowering of temperature to the extent of 34.5° Cent. (94.1° Fahr.). This exaggerated depression has not in any case been injurious to the patient. Pulmonary congestion is a danger to be feared and avoided in the use of carbolic acid. Dr. Van Oye has pointed out albuminuria, polyuria, and fatty degeneration, as the possible effect of long doses greatly prolonged. The antipyretic properties of carbolic acid should, the author says, be reserved to overcome high temperature in continued fever, and to prevent the paroxysms in intermittent fever.—*London Medical Record*, June 15, 1882.

CONGENITAL MALFORMATION OF THE RIGHT KIDNEY.—MR. POWELL gives the following account of a necropsy made at the Nottingham Borough Asylum. The subject of the post-mortem was a man aged forty-

five years, who had been a patient in this asylum for little more than a year, suffering from melancholia. His death was due to atrophy of the brain, and had no connection with the abnormality. All the abdominal organs were in their normal positions except the right kidney, which was found lying on the bodies of the fourth and last lumbar vertebræ, as nearly as possible in the median line, and covering the upper part of the common iliac vessels and bifurcation of the aorta. The organ was smaller than was natural, and of an irregularly rounded shape anteriorly, but concave posteriorly and fitting on to the bodies of the vertebræ. At its upper extremity and to the left it was joined to the lower end of the left kidney, which was normal in size and shape, except that the lower end was somewhat elongated and pulled forward. On the anterior aspect of the abnormally placed organ was a fissure running obliquely downwards from left to right, and in this lay the ureter, which passed down in front of the iliac vessels and entered the bladder in its normal position. The right renal artery was derived from the aorta an inch above its bifurcation, and entered the kidney at the upper extremity of the fissure above alluded to. Three smaller arteries springing from the right common iliac also entered the kidney posteriorly. The left kidney had its own ureter, which passed down beneath the junction of the two kidneys on its way to the bladder. The right supra-renal capsule was in its normal position, and consequently some distance away from the kidney. The tissue of both kidneys had to the naked eye a healthy appearance.—*Lancet*, June 24, 1882.

Infectiousness of Tubercle.—M. Giboux has made some new experiments which confirm his results recently presented to the Académie des Sciences as to the noxiousness of the expired air of phthisical patients. Placing in two cages young rabbits of the same litter, from perfectly healthy parents, as shown by post-mortem examination, he caused them to respire daily for two or three months twenty to twenty-five litres of expired air from persons in the second and third stages of phthisis, passing, in one case, the air first through cotton wool. The animals which were thus protected by the cotton wool preserved their health, as shown by autopsy, during the entire course of the experiment; while the animals which inspired the infected air directly soon lost their appetite, suffered from diarrhœa, became emaciated, and after death tubercles were found in the liver, spleen, and apex of the lungs.—*Revue Scientifique*, June 3, 1882.

Recovery from Hydrophobia.—A case of recovery from an attack of hydrophobia was related to the Académie de Médecine at the meeting of June 13, by M. G. Denis-Dumont, of Caen. The patient was a man, thirty-eight years of age, of strong constitution and previous good health, who was bitten on April 16 on the forearm by a rabid dog, which had bitten, the same day, a woman and two children. The woman died of hydrophobia on May 20, and the news of the death profoundly impressed the patient, who became restless, anxious, affected with extraordinary thirst, and complained of sore throat and of difficulty in swallowing. He refused all drink which was offered to him, manifested a tendency to bite persons and objects around him, and presented convulsive attacks of the character so frequently met with in hydrophobia. He was taken to the hospital on May 23, and none of the medical men in attendance had any doubt that he was suffering from hydrophobia. The treatment employed consisted in hypodermic injections of a centigramme of pilocarpine, which caused an abundant diaphoresis and salivation. At the same time a draught was given of two drachms of bromide of potassium, four drachms of chloral hydrate, and an ounce of syrup of codeia (whether at a single dose or in divided doses the report does not state). The symptoms presented a rapid amelioration, and on the 30th of May had entirely ceased. It seems open to question whether or no the case was one of genuine hydrophobia. When the symptoms commence with mental disturbance, distinctly excited by such intense apprehension of the disease as is excited by the news of the death of another person bitten at the same time, the case cannot be regarded as affording conclusive evidence on the therapeutical question. M. Bouley, however, announced his intention of communicating to the Académie at the next meeting another case of hydrophobia in which recovery followed the use of pilocarpine.—*Lancet*, June 24, 1882.

Albuminuria after External Applications of Tar and Iodine.—Dr. Jacubasch (*Charité-Annalen*) found that after having made applications of a tar-vaselin (picis liq., one part; vaseline, ten parts), to a child seven years old for eczema, albuminuria appeared, and continued for seven days after discontinuance of the applications. On repeating the application the albuminuria reappeared and continued for six days. It was proven that the vaselin alone would not produce this effect. Dr. J. noticed the same effect to be produced on two other children aged six and eight years.

He also observed that albuminuria and fever followed the application of iodine to a swollen scrofulous gland in a girl four years of age.

Albuminuria, after pencilling with iodine, had already been observed by Simon and Budin, but only in children. J. noticed the same in a lady twenty-five years of age, seven hundred square centimetres of whose skin had been pencilled with iodine. Salts of iodine do not produce this effect, nor will it follow if the surface to which the iodine has been applied be washed with a solution of common salt or soda.

Von Lassar reports a case of fatal albuminuria in a man, following an application of petroleum to the whole surface of the body, on account of itching. Lassar has experimented by rubbing petroleum into the skins of animals. He found that it caused rapid degeneration of the epithelium of the uriniferous tubules. —*Physician and Surgeon*, June, 1882.

Absorption from the Bladder.—Dr. B. London, of Carlsbad (*Berliner klin. Wochen.*, No. 11, 1881), has made a series of chemical and histological investigations in Ludwig's laboratory, in order to determine the disputed point whether the mucous membrane of the healthy urinary bladder does or does not permit absorption. He found, on injecting into his own bladder weak solutions (½ per cent.) of chloride of lithium and iodide of potassium, that traces of these could be detected in the saliva. As it has been said that distention of the bladder favors absorption, possibly by producing some mechanical alteration in the epithelium, he made a number of observations on the bladders of dogs, and found that no degree of distention caused either displacement or a solution of continuity of the epithelium, on account of its extraordinary elasticity, but that there was a decided change in the shape of the epithelial cells.—*London Med. Record*, June 15, 1882.

Simple Means of Detecting Trichinæ.—According to Prof. Phin, the parts of an animal that should first be examined are the diaphragm, tenderloin and muscles about the head and throat. In a ham, the most likely place is that at which the muscle ends in a tendon. Cut off a thin slice with a very sharp knife, or with a pair of scissors curved on the flat. This thin

section should then be soaked for some minutes in acetic acid, spread out on a thin piece of glass, and covered with another similar piece. These two slips are then pressed together. A compressorium, by means of which the plates of glass are forced together by a lever and screw, answers admirably. But better still he finds the trichinoscope, which is a compressorium holding the two glass slips, but fitted with a simple microscope on a sliding frame, which permits the examination of the specimen in each part. A thin piece of flesh, moistened with a mixture of equal parts of acetic acid and glycerine, is placed on the lower plate, and spread by means of needles fixed in wooden handles. The upper plate is then brought down on the lower one, and the screw is turned into the slot in which it fits. By turning the nut any degree of pressure may be brought to bear on the flesh, which thus is rendered so thin and transparent that any trichinæ present will be readily brought into view.—*Boston Journ. of Chemistry*, June, 1882.

THE RED COLOR PRODUCED IN DIABETIC URINE BY CHLORIDE OF IRON.—Ever since Gerhardt directed attention to the fact, it has been well known that, in many cases of diabetes, the urine became red on the addition of chloride of iron. The substance to which this reaction appears to be due is usually known under the name of ethyldiacetic acid. On the addition of water it breaks up into acetone, alcohol, and carbonic acid; and as these substances are frequently present in diabetic urine, Gerhardt supposed that the substance to which the red reaction of the urine is due subsequently broke up into these three.

There are, however, other substances which, when present in urine, lead to a similar coloration on the addition of chloride of iron, among which may be mentioned salicylic acid and its salts. To distinguish the reaction of ethyldiacetic acid from that of other substances, VON JAKSCH (*Zeitschr. für Heilk.*, Band iii.) points out (1) that, when the urine is boiled for five or six minutes, the ethyldiacetic acid becomes decomposed, and no longer gives the red reaction; and (2) that, when that substance is extracted from the urine by shaking with ether, and the ethereal solution rendered red by the addition of the salt of iron, the red color disappears gradually after standing for a few days. These reactions are sufficient to distinguish ethyldiacetic acid; but a good many others are given, for which the original paper must be consulted.

The results of the clinical examination of a large number of urines are given with some detail. In regard to the iron reaction in diabetic urine, Von Jaksch points out the following facts. 1. In all cases where the patient died comatose, the urine gave the reaction. 2. The reaction occurred very frequently without any coma being present. Its presence does not depend upon diet, and particularly not upon the meat-diet of diabetics. 4. Neither the administration of such medicines as Carlsbad water, cod-liver oil, lactic acid, mannite, lichenin, nor of ethyldiacetic acid or acetone, caused the appearance of the red reaction in the urine.

Not only in diabetes, but also in scarlatina, measles, and other acute exanthemata, the author detected the presence in the urine of the substance which gives this red reaction.—*London Med. Record*, June 15, 1882.

OPIATES AND PERISTALSIS.—PROF. NOTHNAGEL, of Vienna, recently communicated to a German society the results of experiments on the action of opium and morphia on the intestine. The constipating power of these drugs appears due to their being irritants of the splanchnic, the inhibitory nerve of the intestine. That nerve is specifically influenced by morphia, just as the vagus, the inhibitory nerve of the heart, is acted upon by digatalis; in fact, in both cases, small doses excite, large doses paralyze. It was observed, in a discussion on this question, that the peristaltic action of the intestines is not necessarily the same in man as in animals. Antiperistalsis does not appear to occur in the latter; in our species it is known to exist; though, when obstruction exists, peristalsis in the ordinary direction is quite sufficient to account for fecal vomiting. Dr. Rosenstein, however, had seen chronic fecal vomiting in a patient of his where no mechanical obstruction could be found. Prof. Preyer stated that he had seen antiperistaltic movements of the small intestine in animals, and pointed out that the filling and emptying of the cæcum, especially of the very long cæcum of some animals, could only be effected by alternate peristalsis and anti-peristalsis.—*Brit. Med. Journ.*, May 27, 1882.

ARTIFICIAL DRUM-MEMBRANES, AND ESPECIALLY THE COTTON PELLET.—DR. GRAF reports seven cases in which he employed several forms of artificial drum-membranes, and thinks, if any conclusions can be drawn from so few cases, that the artificial drum-membrane is useful only in cases of large perforations, with a tough mucous membrane of the drum-cavity, where there is but little or no secretion, and great diminution of hearing. He thinks he can also testify to Moos' observation, that the artificial drum-membrane sometimes restores bone conduction, but in one instance this was not the case. He also agrees with Bezold that a layer of boracic-acid powder causes increased hearing by acting as an artificial drum-membrane. As a general thing, however, he is inclined to give the cotton pellet the preference. Its therapeutic effect is also in its favor. It does not seem to be of great importance whether the pellet is used dry or moistened with glycerine, vaseline, etc. This depends upon the peculiarity of each case.—*Archives of Otology*, June, 1882.

POST-MORTEM SIGNS OF DROWNING.—From an analysis of one hundred and seventy cases of drowning, of which the appearances are arranged in tabular form, DR. F. OGSTON, JR., draws the following conclusions:

1. When an external examination of the body only is allowed, if abundance of water pours from the mouth on turning the corpse face downwards, and if white watery froth is found at the mouth and nostrils, or if it may be made to issue from them on compressing the chest, we may be justified in giving an opinion as to the probability of drowning, especially when the accessory signs, viz., rosy redness of the face and front of the chest, gooseskin, and bleaching and corrugation of the hands, are well marked, presuming always that no lethal injuries are seen on the body which would appear to have been inflicted before death, and no traces of corrosive action, etc., from poisons be observable about the lips, hands, clothes, etc., but that to justify us in giving a more positive opinion we ought to have furnished to us a detailed account of the locality in which, and the circumstances under which, the body was observed before its removal to the place where it lies for examination.

2. That where a complete inspection of the body is permitted, we may give a more positive opinion when, in addition to the external appearances, water in marked quantity, mixed with white watery froth, is found in the lungs and stomach, and also, perhaps, when a large quantity of watery fluid is seen in the pleural cavities, when sand, seaweed, etc., are found in the bronchi, or even in the trachea, when the lungs are bulky or protrude on the removal of the sternum, and when the blood within the heart is wholly fluid—especially when with these signs we find marked appearances of asphyxia in the heart, lungs, liver, etc.—*Edinburgh Med. Journ.*, April, 1882.

Treatment of Strumous Glands.—The treatment of chronic caseating strumous glands has undoubtedly been improved in quite recent times. In the earlier stages the external application of iodoform in the form of its collodion is frequently of marked service, and when suppuration has taken place the thorough local application of powdered iodoform and the enucleation of the glands are of great value in cutting short the affection and producing a quick recovery. In a paper in the *Central. f. Chirurg.*, Dr. von Lesser points out that the disease in the glands often assumes the form of small caseous foci, which may become encapsuled and possibly calcareous, but are more likely to lead to suppuration, during which they are extruded, or to general tubercular infection. In view of these events he has, while the glands are still only indurated, attempted to enucleate these caseating portions of the glands. His operation is thus performed: Fixing the gland and pushing it forward under the skin with the finger and thumb of the left hand, he makes a small puncture through the skin and into the gland with a narrow knife. Through this wound he passes a small sharp spoon and scrapes the interior of the gland. The soft cheesy portions readily yield and come away, while the more healthy parts of the gland prove more resistant. If several glands lying close together are enlarged, he operates on them all, or on several through one skin wound, the spoon being pushed into one after another. By this means the disease is cut short, ulterior dangers are avoided, and unsightly scars prevented. Lesser recommends that the operation should be done with strict antiseptic precautions, and that care should be taken not to wound any large vessel, nor to leave behind in the wound any of the cheesy débris.—*Lancet*, June 24, 1882.

Laparotomy in Purulent Peritonitis.—The patient, a young man, aged 21, operated on successfully by Dr. Schmidt for purulent peritonitis, was shown last year in the Medical Society of the Moscow Military Hospital (*Wratsch.*, Nos. 51, 52). Eight months before, he had been admitted into the hospital for recurrent fever. In the hospital he had three attacks, the last being followed by inflammatory fever, the cause of which was not clear. Six months thereafter the patient came into Dr. Schmidt's hands in a very reduced condition, and with a well-marked exudative peritonitis. He decided to open the abdominal cavity, and, under antiseptic precautions, with the patient under chloroform, he made an incision from the umbilicus to the symphysis. On division of the thickened peritoneum, a large quantity of healthy pus gushed out. As there was no sign of decomposition, the cavity was emptied as completely as possible without washing it out with any antiseptic. Two finger-thick drainage tubes were inserted, the wound sewn up, and a strict Listerian dressing applied. The dressing was at first changed daily, afterwards every five to ten days. The wound healed without a bad symptom, and, in two months from the operation, the patient was recovered. Dr. Schmidt believes that the cause of purulent peritonitis is the escape of low organisms from the intestine into the abdominal cavity. Such may be the case, but certainly in this instance the explanation by a thrombosis, brought about by the recurrent fever, seems to lie nearer to hand. But however that may be, the case is an interesting and encouraging one, indicating that surgical treatment is justifiable in purulent peritonitis, as it is in empyema.—*London Medical Record*, June 15, 1882.

The Treatment of Writers' Cramp.—Dr. Th. Schott, of Nauheim, writes to the *Deutsche Medicinische Zeitung* to claim for his brother (Dr. Aug. Schott) and himself priority in the mode of treatment recently described by M. Romain Vigouroux as Wolff's method, and which was communicated by them to Wolff in 1878. He gives a very clear description of the method, which consists of a combination of gymnastics and shampooing. The gymnastics are active and passive. The latter are performed by the patient alone. They last 20, 30, to 45 minutes. Commencing with the fingers, these are flexed, extended, abducted, and adducted; the thumb is treated separately. Then follow four movements of the wrist, flexion and extension of the forearm on the arm, and finally movements of both arms in four directions. Each exercise should be repeated six to twelve times, and with sufficient effort to redden the face. After each series of movements there should be a short pause. In the active gymnastics the same movements are made, but each must be arrested, or rather opposed by another person, so that for each a distinct muscular effort is required. These exercises should last as long as the preceding series. They should be repeated three or four times a day. In the process of shampooing, the operator oils his hands and the patient's limbs, and commences by light friction over the course of the principal nerve-trunks, from the periphery to the centre, gradually increasing the force of the pressure, and again relaxing it towards the end. This part should last about ten minutes. Shampooing of the muscles is performed by taking the body of a muscle in the hand and rubbing it longitudinally and transversely, without compressing it too much on the subjacent bone, commencing with the hand and finishing with the shoulder. The duration is the same as for the nerves. Care must be taken to avoid bruising, which does harm. A single daily shampooing is enough. The improvement which is manifested by the third or fourth week should not cause a cessation of these exercises, but they should be continued for six or eight weeks to ensure a complete cure. In the early period of treatment the patient should abstain from work, and go back to it gradually, avoiding all cause of fatigue. To prevent relapses, Dr. Schott recommends daily employment of the passive exercise for some weeks, and the use of the local cold douches suggested by Esmarch. He has cured all his patients, and has seen no relapses. Most of them were the female pupils of the Conservatoire of Music, at Frankfort, sufferers from pianists' cramp.—*British Medical Journal*, May 27, 1882.

Peculiar Skin Eruption Occurring during Pregnancy.—Mr. R. J. W. Oswald reports the following remarkable case: Mrs. A., aged forty, the mother of five children, was confined of a healthy male child on March 7, 1882. She had had no child or miscarriage for eight years and three months previously. When about five months pregnant with this last child she noticed a squamous eruption appear on the upper third of the forearms, not affecting the flexures of the elbow-joints. This eruption gradually became worse, the skin was indurated and raised, and eventually both forearms and hands were affected. Almost concurrently with this the lower limbs showed the same peculiarities, with some variation, however. The enlargement was very great, almost to twice the natural size, accompanied with œdema. The skin was very rough and hard, and appeared similar to "elephantiasis." About two months before the patient was confined, larger bullæ appeared on the lower extremities, but at no time were the upper limbs thus affected. Some of these bullæ burst and formed hard thickened crusts, from which exuded a thin glairy fluid. The pain accompanying this affection was very severe, and the patient was unable to go about her household duties for fully three months previous to her confinement. Immediately after the confinement the

skin of the forehead, face, neck, and upper part of the chest, which up to that time had been free from blemish, began to be squamous and indurated, and very much thickened, but no bullæ appeared at any time. Both anæsthesia and hyperæsthesia were present. She is now (seven weeks after her confinement) better in some respects, although there are still a few bullæ on the legs, and the skin still shows to a slighter extent the peculiarities just described. The patient is, no doubt, of a rheumatic diathesis, but whether this, combined with the great changes the system undergoes during pregnancy, has helped to cause this eruption he could not say. The only treatment adopted has been absolute rest, and the administration of alkalies. Prèvious to her confinement eight years ago the patient had a similar eruption on the forearms and hands, and the legs and feet were affected also about two months before the confinement. In about three weeks after this the skin was quite clear again, and the severity of the attack was not nearly to the extent as in the present instance.—*Lancet*, June 10, 1882.

THE FUNCTIONS OF THE EUSTACHIAN TUBE.—In his earlier experiments Fournié came to the conclusion that the Eustachian tube was open in the state of muscular rest. The manner of proving this is somewhat peculiar. He took two glass balls, which were attached by a glass rod 2 mm. thick. In one of the balls there is gas; the other is closed. Since he could not smell that gas was in the first ball, he considered it as proven that by open tubes no air went into the drum-cavity, it must therefore be driven into it by the action of the muscles. Later anatomical considerations (*Rev. Méd.*, No. 38, 1881) have convinced him that the tubes are widest opened at the beginning of the act of deglutition, brought about by the action of the tensor veli and the m. glosso-palatinus. In the latter part of this act the tubes are compressed by the tensor tubæ, and the air contained in them forced into the drum-cavities.

How erroneous the conclusions are which Fournié draws from his alleged physiological facts, is evidenced by his discussion of the usual methods of inflation. According to Fournié, Toynbee's experiment does not produce a rarefaction but a condensation of air in the drum-cavity. A simple inspection of the drum-head during this experiment would have convinced him of the contrary. In Politzer's experiment the forcing of air into the tube is of but little moment. In Lucæ's or Gruber's procedure the passage of air through the tubes, according to Fournié, is impossible, as the tubes are closed. The best procedure is now found: "The procedure of Edward Fournié." Open the mouth before a looking-glass, depress and contract the velum palati, until above and before the anterior arches two small dimples are formed; in that moment the tubes are opened and the air enters the drum-cavity by itself.—*Archives of Otology*, June, 1882.

HOANG-NÀN IN HYDROPHOBIA.—In a recent case of hydrophobia in Paris, M. GINGEOT administered hoang-nàn, a Tonquin remedy employed in the East for a variety of diseases, and especially for hydrophobia. It is a product of the Strychnos gautheriana, so-called after the missionary who first transmitted a specimen to France. According to Wurtz the bark contains some strychnine and a still larger quantity of brucine, and its action on animals is the same as that of these two alkaloids, with the difference, however, that the effects are manifested first on the hind limbs, then on the trunk, and lastly on the fore limbs. Another difference from brucine is that the convulsive spasms always cease a short time before death. In hydrophobia, according to Lesserteur, it should be freely given, until the patient experiences a sense of general malaise, giddiness, and nervous movements of the jaw. Vinegar should be given with it to dissolve the active principle in the stomach. In M. Gingeot's case the progress of the disease did not appear to be in any way influenced by the treatment, but the first doses were vomited, and the patient died shortly after two hypodermic injections of hong-nàn had been administered.—*Lancet*, June 17, 1882.

PIGMENTARY HYPERTROPHIC CIRRHOSIS IN DIABETES MELLITUS.—MM. HANOT and CHAUFFURD report the histories of two cases in which a bronze coloration of the skin, analogous to the condition observed in Addison's disease, but without pigmentation of the mucous surfaces, occurred during the cachectic stage of diabetes mellitus. At the autopsy there was found a hypertrophic cirrhosis of the liver, with numerous new formations of bile ducts and pigmentary atrophy of the hepatic epithelium. The authors attribute, with some reserve, these complex lesions to three successive influences: first, the lesion producing the diabetes; then the alteration of the blood thereby produced, and finally the irritant effect produced by the arteritis.—*Gaz. Hebdom. de Méd. et de Chir.*, June 9, 1882.

GLANDERS IN THE HUMAN SUBJECT.—In a recent number of the *St. Petersb. Med. Wochenschrift*, DR. ZDEKAUER describes a case where the clinical symptoms of glanders were observed, although no distinct history of infection could be obtained. A lady, aged 46, and in very good health, was attacked, at the beginning of January, with swelling of several large joints, and high fever. At the end of three weeks, the temperature continued over 104°, with no eruption, slight enlargement of the spleen, and very feeble pulse. Dr. Zdekauer diagnosed "latent blood-poisoning complicated by rheumatic polyarthritis." On January 26, the face became œdematous, with pustules as large as a bean; there were great lividity of the lower eyelids, no glandular swellings, and a typhoid condition. On the next day, the face was enormously swollen, and large grayish swellings, with dilated lymphatic vessels between them, covered the left lids, the nose, and the mouth. Several pustules, of the size of cherries, with livid bases, were found on the arm; the patient became comatose, and died in the evening.—*British Medical Journal*, May 27, 1882.

PYROGALLIC ACID IN THE TREATMENT OF VENEREAL ULCERS.—DR. ANDRIEU (*Thèse de Paris*, 1881) says that pyrogallic acid has been introduced into therapeutic use by Dr. Jarisch, of Vienna. Since then M. Vidal at Saint Louis, and M. Terrillon at the Lourcine Hospital, have applied it successfully to the treatment of soft chancre. The formula used at the Lourcine is as follows: Starch, 40 grammes; vaseline, 120 grammes; pyrogallic acid, 40 grammes. This ointment should be used fresh, and kept in a stoppered bottle. To remedy the inconveniences of dressing venereal ulcers with fatty bodies, M. Terrillon has substituted for the ointment a powder composed as follows: Pyrogallic acid, 80 grammes; starch, 80 grammes. This powder is blown on the part by means of a small bellows. Nevertheless, a certain number of cases reported by Dr. Andrieu in his thesis tend to show the superiority of the ointment over the powder. If one application be made daily, the duration of the treatment is notably abridged, in comparison with the methods generally employed. It is sometimes necessary, when the ulcer is very extensive, to make two applications; but the latter is the exception. After the second application, the chancres will have lost all their virulence.—*London Med. Record*, June 15, 1882.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE, ... $5.00.
SINGLE COPIES, ... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made at the risk of the publishers, by forwarding in REGISTERED letters.

Address, HENRY C. LEA'S SON & CO.,
NOS. 706 & 708 SANSOM STREET,
PHILADELPHIA, PA.

SATURDAY, JULY 22, 1882.

THE DANGERS OF ATHLETIC SPORTS.

LAST week we alluded, in terms of the highest praise, to the recent popularity of athletic, and especially of summer, sports. But there is another side to the question. "Nothing venture, nothing have," saith the old proverb, or, transposing it, the having implies a venturing. Every climb means peril of a broken limb; every swim the possibility of drowning; every ride may become a runaway.

Many games involve actual danger, only to be avoided by an alertness the result of long practice and by suitable precautions. Witness the mask of the base-ball catcher and the fencer, the gloves of the boxer, the button on the foil. But strength only comes from perils faced and mastered. The "milk-sop" may neither break his bones nor his neck, but his physical as well as his mental flabbiness involve passive dangers less heroic and less apparent than those of the athlete, but not the less certain and, it may be, deadly.

But the dangers from blows and falls are patent to every one, and must be, as it were, anticipated and provided against by those engaging in such sports. We wish now to raise anew a warning voice as to less apparent dangers—dangers, in fact, unknown save to the physician.

One source of evil we alluded to but lately—that of heat exhaustion. The season for out-door sports is the hot season. The boat races, the cricket or the base-ball matches are in the broiling sun, and if brief, as in rowing, are fierce and impetuous to the last degree; if long, as in ball and cricket, hours may be spent in the heat, and the better the player the longer he is at the bat. But it is often in the previous training, or rather over-training, that the danger lies. The college man, accustomed to only moderate exercise and to ordinary food, suddenly undertakes long walks, swift runs, and repeated rows; restricts and alters his ordinary food; changes more or less his habits as to sleep and tobacco, and, it may be, other stimulants—changes which, though in themselves good, are none the less disturbances of his ordinary equilibrium—loses fat and gets down to "fighting weight." To most men such a course of training means vigorous health; but every now and then either a man goes to the extreme and overdoes it or lacks the ordinary toughness of fibre, and in the final short but sharp struggle he becomes exhausted and faints in his place or when the trial is over.

But there are other dangers still. Train as one will, no practice ever equals the race in the excitement and the intense exertion of the competition; a running mate is needed even to make Goldsmith Maid do her best. Each time and especially at the race, with the exertion comes the need for more blood sent quickly to all parts of the muscular system. The heart must do more work, and do it suddenly and effectively. With the growing biceps the cardiac muscle grows too, and enlargement of the heart, sometimes even acute in its onset, is not an uncommon result; or, if the heart responds but imperfectly to the oft-repeated and prolonged demand, the form of irritable heart, so well described by Da Costa, in soldiers, will often set in.

But the mischief does not stop even here. With increased blood supply the lungs must be overstrained to receive and oxygenate the blood so suddenly thrown upon them, and also by the mechanical effects of the violent respiration. Under the sudden or continued pressure the delicate air cells not seldom give way and emphysema results. In the fierce struggle at forty-six strokes to the minute, what wonder that the race is lost and with it not rarely the possibility of a brilliant future for one or more young lives.

Women are certainly less apt to suffer from vigorous sports than men; yet not a few overdo. A young girl at school or engaged in home duties and leading a semi-sedentary life for six days in the week, on a Saturday will walk five or ten miles; or spend an entire afternoon at tennis or croquet. It is the same disproportion that does harm. If every day she walked three to five miles, the ten would do no harm. Physical development must come gradually and not spasmodically. The first days of a summer's holiday in the mountains do not give the strength for climbing, that will come in time. *Petit à petit* was the motto of the French knight, at the foot of a mountain with his pick-axe. Particularly do girls and often women harm themselves by over-

exertion at the menstrual period, and especially of course in winter. Modesty forbids the true excuse, candor rejects a false one, and off they go with aching backs and throbbing heads as merry as the merriest; walking, running, skating, exposed to dampness, and cold, and fatigue, when they should be at rest, warm and dry. Health should be had at the cost of any pleasure, and a sister of Scheherazade surely can always find or make a valid excuse.

IODOFORM IN VENEREAL PRACTICE.

LIKE most other new and useful remedies, iodoform, which in certain properly selected cases acts almost like a specific, has come to be prescribed so indiscriminately that it often fails to produce the results expected from it, and consequently suffers unjustly in general estimation.

Leaving aside for the present its use in antiseptic surgery, a subject now being actively discussed, it may not be without avail to mention in a few words the indications for its employment in venereal practice, and the limitations within which, in such cases, it is likely to prove beneficial.

Its chief value, and that which first brought it prominently to the notice of the profession, is in its application to unhealthy or chancroidal ulcers of the genitals, upon which its combined sedative and alterative action exerts the happiest effect. In this respect no other drug can be compared with it, and in its power to relieve pain, to prevent offensive decomposition of discharges, and to stimulate the surface of such ulcers to granulation, it is certainly unequalled; there, however, its usefulness stops; it will not retard the growth of a large, indurated, infecting chancre, it will not arrest phagedæna, it will not remove venereal warts, nor materially affect an inflamed gland; and yet it is an every-day occurrence to find it prescribed for one or the other of these affections to the neglect often of the proper remedial measures.

The chief objection to its use is its pungent and to some persons peculiarly disagreeable odor, which it is almost impossible to conceal. Wood-charcoal, petroleum, oil of eucalyptus, glycerine, alcohol, tannin, various perfumes, and strongly odoriferous drugs, have been tried with greater or less success, but the iodoform always asserts itself sooner or later. For ability to "hang around" anything it is once applied to, it far exceeds "the scent of the roses," or any other scent with which we are familiar. The most effectual plan of disguising the fact that iodoform is in use about the genitals, is one employed by a practitioner of this city, who recommends such patients to spread some of the ointment upon a piece of muslin and bandage a finger with it, thus apparently furnishing to all inquiring friends conclusive ocular evidence as to the source of the smell.

Internally iodoform has been proved to be of great use in those cases of obstinate tertiary syphilis in which other forms of iodine have lost their power. In doses of from a quarter to a half a grain, four times daily, gradually increased if the stomach tolerates it, it will sometimes exert a most excellent influence on old syphilitic ulcerations, fissures of the tongue, obscure cerebral or hepatic symptoms, or other late manifestations of the disease.

Here, again, we have sometimes known it to be prescribed injudiciously, in the early stages where mercury should have been administered, and in other cases in which the same results might have been attained by iodide of potassium, and with far less danger of gastro-intestinal irritation.

It should never be used internally in late syphilis unless the other iodides have failed, but if it is then given cautiously, and if care be taken to associate its administration with the taking of food or the ingestion of barley water or some other mucilaginous drink, it will often be found of great benefit.

Iodism and unpleasant cerebral symptoms result from its continued use in full doses, and, as in a case reported by Oberländer, have appeared when only five grains had been taken.

THE ASSOCIATION FOR THE ADVANCEMENT OF MEDICINE BY RESEARCH.

SUCH is the clear but cumbrous title of a society which has been, as it were, compelled to exist by reason of the repeated and fierce attacks of the anti-vivisectionists in England. Its purpose is not so much, perhaps, the endowment of research as its guidance and protection. The Royal Society and the Committee of the British Medical Association on Scientific Grants both supply the means to scientists not so happy as Mr. Darwin in being plethoric in purse. But this Association is especially "to meet promptly any attack from outside upon the invaluable labors of competent investigators," as Dr. Wilks, the Treasurer, puts it. In case of any doubts arising in the mind of the Home Secretary as to the advisability of granting any license for research by experiments, here is a body to which he may confidently appeal to determine whether the proposed investigation be needful, the investigator competent, the methods wise and humane. If the law be invoked to prevent progress by research, the Association will also wield the same weapon to defend the scientists thus threatened. The education of public opinion, however, will be, perhaps, its chief function. Even in this country such education is sadly needed, but in England it is imperative. If a change is not soon effected in public opinion and in legislation, research must come to an end, and sci-

entific medicine must stop. The publications of the Association, the pamphlet of Mr. S. Gamgee on *The Influence of Vivisection on Human Surgery*, and the published addresses and papers of Dalton and others in this country, will do much to put the matter in its true light, and overcome the prejudice which exists as the child of ignorance and false sentiment.

The Association starts, we see, with over £1000 in its treasury. We wish it the best success, with the added wish that no such association shall ever be needed in this country by reason of any similar opposition to scientific research.

SEWERAGE IN PHILADELPHIA.

IN our issue of June 17th, we directed attention to the unsanitary condition of the sewerage of Philadelphia, and specified some of the more glaring defects in the system. Since then Councils have passed two ordinances, which, if faithfully administered, will have the effect of greatly improving the character of all future work of a certain class. The one requires "that all sewers hereafter to be built, and of which the area required shall be less than that of a circular sewer of four feet diameter, shall be of the section known as oval or egg-shaped;" the other provides for the appointment of inspectors of the construction of branch sewers, drains, and inlets, who are to be held responsible for the faithful execution of the work in strict accordance with the specifications and contract.

As an evidence of a livelier and more intelligent interest in the solution of a question vitally connected with the preservation of the public health, this legislation is indeed most promising. It undoubtedly will be productive of good results. But its object relates solely to the design and character of works hereafter to be constructed, and affords no relief whatever for the blunders and evils with which the present system is burdened.

It was hoped that, in the apportionment of the handsome surplus of over one million dollars among the most needed permanent improvements of the city, a reasonable amount would have been set apart for the purpose of commencing the thorough reconstruction of the sewerage works in accordance with the requirements of the highest standard of modern skill and knowledge. This course would have been timely and judicious, and there appears to be no justifiable excuse for its neglect.

BEEF-TEA.

WE had occasion to observe a short time ago that our long-prized and extensively-employed beef-tea was, according to the recent opinion of some physicians, of no more value than urine, which it was said very closely to resemble in composition. It is more pleasing for us now to state that, according to the researches of KOBERT (*Archiv f. Exper. Pathologie u. Pharmakologie*, Bd. xv., s. 22), which have been conducted in the laboratory of Schmiedeberg, at Strasburg, the kreatin which exists abundantly in all extracts of beef has a remarkable effect on the muscular system, inasmuch as it increases its actual power and greatly extends its capability of continuous work. His experiments were made on frogs, and of many substances tested, besides kreatin, only hypoxanthin and caffein possessed a similar action; and hypoxanthin is likewise a constituent of beef-tea. Beef-tea, therefore, if not so highly nutritious as it is generally assumed to be, is not yet so entirely useless as some observers would have us believe. The feeling of strength which its employment gives must, apart from its actual value as a nutrient, be of great service in the treatment of the sick and convalescent.

T HECURIOUS HISTORY OF AN ANATOMICAL SPECIMEN.

WE venture to think that few of our readers know the romantic history of one of the specimens in the remarkable collection of preparations illustrating the anatomy of the ear in the possession of the College of Physicians of Philadelphia. Prof. Joseph Hyrtl, who prepared the specimens (and from whom they were bought), had such relations with scientific men and dealers that he was able to procure many unusual specimens, sometimes by purchase as great rarities not to be "ordered" as wanted; sometimes by exchange; sometimes as presents. The history of some of these is found in a little pamphlet he published in 1873. As an example of the first, the skull of the gorilla cost one thousand francs, besides the labor afterwards bestowed on the preparation of the ear-bones and labyrinth. As examples of the last are the specimens from the elephant, rhinoceros, hippopotamus, and others presented to him by De Blainville. That from the hippopotamus has, however, a very peculiar and amusing history connected with it. No living hippopotamus had been brought to Europe since the time of the Romans, and the anatomy of its viscera was entirely unknown, when the French government sent M. Arnould d'Abbadie as Minister to the King of Schoa (Abyssinia). The Academy, before he left, expressed an earnest wish that he would send them the viscera of a young hippopotamus in Gannal's solution. The minister obtained the coveted prize with unexpected and most creditable tact. On his arrival he found his sable Majesty laid up with articular rheumatism, and was soon besought to lend his services, as in the Orient all the Franks pass for physicians. M. d'Abbadie answered resolutely "assuredly." "Bring me the remedy," said the King, "I would give my crown to be well again." "Nothing is easier; the

remedy is to be found in your own country; it is hippopotamus fat." "Fetch a hippopotamus," cried the King in haste to his attendants. "Not so fast, your Majesty, not so fast; it must be the fat of a female, and of a female that is pregnant," said the wily ambassador.

Diplomacy clearly has its place even in science. Huntsmen were immediately sent out in all directions, and soon returned in triumph. D'Abbadie rubbed the fat on the joints of the King and cured him! History saith not anything as to his fee, but she does record the fact that the fœtus was sent to the *Jardin des Plantes*. There De Blainville allowed Hyrtl to remove one of the temporal bones, and so the College of Physicians has the labyrinth of the hippopotamus of Schoa.

MEDICAL DANGERS FROM CONGRESSIONAL LEGISLATION.

CONGRESS having appropriated $20,000,000 for rivers and harbors, and we forget how many more millions for public buildings, and refused a paltry few thousands for the beneficent work of the National Board of Health, and nearly crippled the National Medical Library for want of $5,000, now proposes at the fag-end of the session to tackle homœopathy and other irregular schools of medicine. Mr. Cameron, of Pennsylvania, has introduced a joint resolution making it a misdemeanor punishable by a fine of $500 and dismissal from office, for any officer to discriminate for or against any school of medicine. Observe the word *any*. Thomsonians, Eclectics, Botanics, Homœopaths, the men whom Buchanan and Paine foisted on a suffering public, are all, at one fell swoop, to be made eligible to the Medical Corps of the Army, Navy, and Marine Hospital Service!

It would seem that Mr. Cameron already had enough political troubles to satisfy most public men. But they only appear to whet his appetite for more. If we really thought his action a serious menace, we should have something to say on the point; as it is, we simply call attention to it as a cheap bid for a certain kind of popularity.

THE DERIVATION OF "TROCHANTER."

A VERY curious series of errors occurs in our dictionaries as to the derivation of the word "Trochanter." They define the English medical term correctly, but give an entirely incorrect definition to the Greek word from which it is derived. Worcester derives it from the "Greek τροχαντηρ, the ball on which the thigh-bone turns in its socket," that is to say, the head of the bone. Webster says, "the ball on which the *hip*-bone turns in its socket," which is simple nonsense. Liddell and Scott, whence doubtless they both took the definition, use precisely the same words as Webster, and give as authorities, "Galen; Epigramma apud Sextum Empiricum M. I. 316; Julius Pollux II. 187; Hesychius."

We have taken no little trouble to verify the references, and find that not one of them justifies the error. Kühn's edition of Galen is in the Library of the College of Physicians, and the other three are in the Loganian Library at the Ridgway Branch of the Philadelphia Library.

Hesychius speaks of the trochanter as "the outside protuberance of the head [*i.e.*, upper end] of the thigh."

Sextus Empiricus quotes from some unknown writer, who uses the word, not very clearly, in speaking of the legs, extending as far as the trochanters, "λνία βᾶσα τροχαντήρων ἀχρι."

Pollux, in the *Onomasticon*, says (we give the Latin translation), "ossium vero circa femoris caput prominentia trochanter nominatur." "The prominence of bone about the head of the femur is called the trochanter."

But Galen's use of the word is still clearer, and we believe most other Greek writers also use the word correctly. Thus in the *De Ossibus ad Tirones*, ch. xx., xxi., and again in the *De Anatomicis Administrationibus*, Lib. ii., Cap. vi., he repeatedly refers to the head of the femur, τὴν κεφαλὴν τοῦ μηροῦ; the neck of the femur, τὸν αὐχένα τοῦ μηροῦ; the great trochanter, τὸν μέγαν τροχαντῆρα; and the lesser trochanter, τὸν μικρὸν τροχαντῆρα; and even distinguishes correctly the muscular insertions into different parts of the great trochanter. We trust that our dictionaries will correct the error.

PILOCARPINE IN HYDROPHOBIA.

IT has been rumored in Paris, lately, that M. BOULEY had cured two cases of hydrophobia by the subcutaneous injection of pilocarpine. It turned out, however, that the cases were probably not examples of hydrophobia. The Paris experience with this remedy has not been fortunate. Prof. Seé has used it in one case without success; and Dujardin-Beaumetz, in no less than six cases of the genuine disease, with equal ill-success. Indeed, the latter affirms that pilocarpine rather increases the severity of the symptoms than affords any relief. Experience, then, is decisively against the administration of this remedy in hydrophobia. The subject deserves mention here merely to prevent the loss of valuable time in the treatment, for, whilst pilocarpine has no curative effect, it rather increases than diminishes the sufferings of the patient.

REVIEWS.

Manual of Diseases of the Skin, with an Analysis of Eight Thousand Consecutive Cases, and a Formulary. By L. Duncan Bulkley, A.M., M.D., etc. 12mo. pp. 312. New York: G. P. Putnam's Sons, 1882.

This little work fills a vacant place in American dermatological literature. Arranged essentially according to the classification of the American Dermatological Association, it is in accord with the larger and more scientific works on skin diseases, and this makes it easy for the student who may wish to enlarge his knowledge of these affections, to pass from the primary work to the larger and more complete Treatise.

Introductory chapters on anatomy, and physiology, and on classification, general diagnosis, and etiology, are followed by chapters on the chief diseases of the skin as they are met with in this country, each one being briefly described as to its clinical appearances and distinctive characters, and then the general outlines of treatment are given with reference to the formulary at the end of the volume for particular and suitable prescriptions.

We can cordially recommend Dr. Bulkley's work to the student as excellent within its peculiar sphere, and far superior to the little English manuals of skin diseases which alone have heretofore been available.

Tubercular Disease of Synovial Membranes and Tubercular Disease of Joints. By John Croft. Reprinted from the *Transactions of the Pathological Society of London* for 1881. 8vo. pp. 16, pl. III. London: J. E. Adlard, 1882.

We must confess that this paper is very scientific, but very dreary. Any one who reads it will fulfil a duty, and feel happy when the duty is done. There is truth in it, and valuable truth as a plea for tubercle, both of the synovial membranes and of the joints, but it is truth so utterly unadorned and unattractive as to be very unlively. The style, too, is careless. "In the adjoining room are exhibited microscopical preparations from *six* cases of diseased joints," are the opening words, and the next three lines show that the preparations are from *seven* cases, of which six were tubercular. He refers to the "two last" cases as if the last case and its predecessor were both "last." He speaks of "articular bone" more than once, a variety of bone we never heard of before; and also of "the constitutional diathesis which leads to, or tends to, lead to the deposit," etc., a phrase whose punctuation is as remarkable as its rhetoric. Dr. Greenfield's illustrations are excellent. If scientific writers would but cultivate a reasonably graceful style, and would be clear, sharp, and short, how much would be gained. But we are not all Tyndalls.

SOCIETY PROCEEDINGS.

COLLEGE OF PHYSICIANS OF PHILADELPHIA.

Stated Meeting, June 7, 1882.

W. S. W. Ruschenberger, M.D., President, in the Chair.

Dr. J. T. Eskridge presented the following *Report of Three Cases of Abscess of the Brain.*

Abscess of the brain is of sufficiently frequent occurrence to make the subject of interest to the general practitioner. The cases reported in this paper are all the more interesting because each, due to a different cause, was associated with dissimilar diseases. The first case was associated with cancer in several of the other organs of the body; the second, with chronic meningitis; the third, with apparent facial erysipelas and pneumonia followed by acute meningitis. Detailed cases of brain lesions lose half of their interest, and become almost valueless to students of cerebral localization, when unattended by accurate descriptions of the relations of pathological lesions to ganglia, fissures, and convolutions. I wish to acknowledge the services of my friend, Dr. Charles K. Mills, who took an active part in the post-mortem examination of Case I., and rendered me valuable assistance in accurately locating the lesions in the first two cases.

Case I. *Two Abscesses of the Brain.—1. The larger one, involving the centrum ovale of the postero-frontal and parietal lobes, deeper portions of the gray matter of the anterior parietal convolution, and superior parietal lobule; 2. The smaller, the anterior two-thirds of the lenticular nucleus, and the adjoining portions of the external capsule and claustrum.*

September 8, 1881, Mrs. D., æt. 54, had been a sufferer from headache fourteen years. She had a large frame and carried considerable fat. Excepting the head trouble, she had enjoyed excellent health until two years before, when she noticed a small tumor involving the left mammary gland. This proved to be cancerous, grew gradually, and was removed by a surgeon one year after its first appearance. There had been no return of the growth, although some pain had been complained of in the region from which it had been excised. Her head pain had greatly increased in severity during the last few months.

In the early part of July, 1881, the left arm began to feel weak, and ten or twelve days later, the left leg was similarly affected, but to a less extent. About this time she went to the country for her health. Continuing to grow worse, she returned home during August, three weeks before I first saw her, and was able to walk from the street cars to her house, a few hundred yards distant. A few weeks later I was called in, and made the following notes:

The left leg was almost completely paralyzed, the muscles feeling soft and flabby. The left arm was entirely paralyzed. The muscles of the left side of the face were slightly paretic. The right pupil was normal in size, left slightly dilated, and responded imperfectly to light. There was no paralysis of the muscles of the tongue, palate, or pharynx. The tongue was slowly protruded in the median line, but when it was held in this position a few seconds it became tremulous, a vibratory tremor taking place in individual muscular fibres. Muscular power was impaired in the right arm and leg, but co-ordination was perfect. She had had no convulsions, and there were no muscular twitchings. With the exception of a slight tendency to drooping of the upper lid of the left eye, the ocular muscles seemed to be acting well and in harmony. Sensation was unimpaired on both sides of the body.

Special Senses.—Vision was equal in each eye, and she read Snellen No. 8, held at about fourteen inches. The ophthalmoscope revealed nothing beyond a slight haziness of the right retina. Taste, smell, and hearing were nearly normal, being well preserved for a woman of her age. Speech was unaffected.

The tongue was moist and slightly coated, appetite poor, bowels constipated, not having been opened for several days. The urine was high colored, sp. gr. 1025, but free from albumen. The bladder was tolerant and acted voluntarily. She was restless, did not sleep well, and complained bitterly of pain in her head. The pain was usually dull. Its seats of intensity were at the top of the head and above each temple, being

worse on the right side. She was intelligent, her mind was clear, but being under the impression that her cancer would return, she worried, had become emotional and imaginative. Temperature (left axillary) 99°; pulse 76, full, soft, and regular; respirations 24 per minute.

September 12.—Four days later she was not so intelligent, worried more, and refused to eat. The feet were extended and inverted, the balls of the great toes lying in contact with each other. The internal and posterior muscles of the legs were so firmly contracted that it required considerable force on the part of the attendant to evert and flex the feet, and the effort gave her decided pain. The muscles of the left side of the face were almost completely paralyzed. Swallowing solid or semi-solid substances was so difficult that she refused to eat.

Temperature, right axilla 96°; left axilla 99.4°; right elbow 95°; left elbow 96.7°. Pulse 86; respirations 26 per minute, and largely of the abdominal type. After taking citrate of magnesium, her bowels were opened once yesterday, being the first time in about a week.

13th.—At 11 A.M., the temperature of the room being 80°, after ascertaining her body heat, as indicated in each axilla, I made observations on her cerebral temperature. Hick's surface thermometer was employed and allowed to remain in place ten minutes. The selected stations were as follows: 1. A middle frontal station in the centre of the forehead. 2. A right anterior frontal station, over the right eye, an inch and a half above the brow and the same distance from the median line of the forehead. 3. A left anterior frontal station, similarly located on the left side. 4. A right posterior frontal station, near the external angular process of the frontal bone. 5. A left posterior frontal station, corresponding in position on the left side to that on the right. 6. A right parietal station just above the left ear. 7. A left parietal station just above the left ear. 8. A right Rolandic station, situated on or near a line drawn over the top of the head from the right to the left auditory meatus, and from two to three inches above the top of the right ear. 9. A left Rolandic station situated similarly to that on the right. 10. A right occipital station, one and a half inches to the right of the centre of the occipital region. 11. A left occipital station, one and a half inches to the left of the centre of the occipital region.

Temperature in right axilla 97.9°, in left axilla 98.4°. Pulse 104, weak and unsteady; respirations 24 per minute.

Surface Temperature of the Head.

RIGHT SIDE.		LEFT SIDE.	
Anterior frontal station,	97.3°	Anterior frontal station,	97.7°
Posterior " "	97.8°	Posterior " "	98.1°
Parietal "	97.1°	Parietal "	97.9°
Rolandic "	96.3°	Rolandic "	96.8°

She was unable to void her urine for the first time today. Thirty-two ounces were drawn off. From this time to the date of her death, just two months later, the catheter was daily required to relieve the bladder. She had not eaten anything for two days. Headache was excruciating. One-half of a grain of morphia was required each night to produce sleep, bromide of potassium making her wild and delirious. During the latter part of the day she frequently talked incoherently.

15th.—The temperature of the left Rolandic station was 5.5° higher than that of the right. The intermitting character of the respiration formed a very interesting feature of the case at this time. There was no gradual rise and fall of the respiratory movements as seen in the typical Cheyne-Stokes' respiration. There were twenty-eight shallow respirations per minute. After four or five short and rapid respirations there was an interval of rest of eight or ten seconds; then after about the same number of respirations, came another interval of rest. During the next week, the pain in the head became more intense, and localized in the top of the head and right temple. The bowels failed to respond to various purgatives and enemata.

22d.—The muscles of the left side of the face showed but little loss of power, the pupils were of equal size. The left leg, as well as the left arm, was now entirely paralyzed. The muscular strength on the right side did not fail faster than is usual in one whose general vitality is being lowered. The conjunctiva of the right eye was congested and watery, the sight being but little impaired.

Temperature, right axilla 97.6°; left axilla 98.2°; pulse 68; respirations 12 per minute, and still of the abdominal type. The movements of the abdomen preceded those of the chest, and formed with them a see-saw-like, or to-and-fro, motion, the chest apparently not expanding until the end of inspiration and beginning of expiration.

23d.—Temperature of room 82°; of right axilla 98.9°; left axilla 98.2°; pulse 72; respirations 9 per minute.

Surface Temperature of the Head.

RIGHT SIDE.		LEFT SIDE.	
Anterior central station, 96.3°.			
Anterior frontal station,	95.9°	Anterior frontal station,	96.2°
Posterior " "	95.6°	Posterior " "	97.6°
Parietal "	97.6°	Parietal "	98.1°
Rolandic "	97.0°	Rolandic "	96.8°
Occipital "	96.9°	Occipital "	98.2°

The pulse, although only 72 per minute, was very weak, but regular in time and volume. The intermitting character of the respiration was more marked on this than on the preceding day. Three or four respiratory movements were followed by an interval of rest, lasting from twelve to fifteen seconds. The number of respirations did not exceed four in succession, nor were they, at any time, less than three. The interval, or rest, was not longer than eighteen seconds, nor was it less than twelve. The respirations, which were largely abdominal, had to be counted for two minutes to obtain the average number per minute. If the movements of respiration were looked for at the beginning of an interval, none were seen during the first quarter or third of the minute, and only three or four during the second quarter or third; whereas, during the latter part of the minute, there might be eight, six, or only three respirations. Thus:

Inter.	Respirations.	Int.	Res.	Int.	Res.	Int.	Res.	Int.	Res.		
	4		4		4		4		4	=	20
15s.	9s.	15s.	9s.	15s.	9s.	15s.	9s.	15s.	9s.	=	120 sec.

It will be seen by observing the above tabular view that, if the respirations had been counted during one minute only, eight might represent the breathing frequency per minute; and if those paroxysms of respiration, if I may so term them, had been limited to three respiratory movements each, as they sometimes were, six, instead of ten, of the tabulated form, could have been set down as the number of respirations. This character of breathing, sometimes slightly increasing in frequency, continued until a few days before her death, when it changed to the so-called Cheyne-Stokes' respiration.

Sighing rarely occurred. The pupils were normal. The bowels had not been opened since the 11th instant, notwithstanding various purgatives and enemata had been given. Croton oil had been given by the mouth until it had produced griping pains, and an emesis of glairy mucus, yet it seemed to have no effect on the

bowels. The patient lived from the 11th of September to the 13th of November without having an evacuation from the bowels. During this period of two months and two days, or about nine weeks, she neither suffered from nausea, vomiting, nor distention of the bowels from gas or feces. Her diet for more than two months just preceding her death was almost exclusively of a liquid nature, she rarely taking any semi-solid food.

28th.—During the last few days the face had been turned to the right, and the head drawn toward the right shoulder. At this time she complained of great pain and soreness in the right and posterior portions of the neck. The parts were hard, swollen, and painful to the touch. An attempt, on my part, to straighten the neck greatly augmented her suffering. Pain was also complained of in the right eye and ear. The former was inflamed, and almost useless as a visual organ, and from the latter there was a constant discharge of yellow pus. The ocular inflammation involved more especially the conjunctiva and cornea. An ophthalmoscopic examination of the right eye was unsatisfactory on account of the hazy condition of the cornea and the uncontrollable movements of the eyes. The watch was not heard by the right ear, except on firm pressure.

October 3.—She was blind in the right eye and deaf in the right ear. The discharges from the eye and ear continued.

13th.—She remained quiet during the day, but required two grains of morphia to induce sleep at night. The hearing in the left ear varied; at times she heard tolerably well with this ear, and at others she was almost deaf. No improvement in the right eye and ear. A semi-choked disk appearance was noticed in the left eye, and vision was nearly gone. The left eye showed no evidence of external inflammation. No discharge was noticed from the left ear.

November 11, 5 P.M.—Temperature, right axilla 95.5°; left axilla 98.2°; pulse 104; respirations, 28 per minute. The right side of the body felt quite cool. The breathing had changed from an intermitting to an irregular character, and constituted what is known as the Cheyne-Stokes' respiration, except that there was no lull, during which the hand could not detect feeble movements of the thoracic wall. The respiratory movements gradually became shorter until they were almost imperceptible, then they gradually lengthened until a full inspiration was taken with considerable effort, followed by a blowing noise. Every paroxysm, or rise and fall of the respiratory acts, included about eighteen respirations. She neither saw nor heard, and was no longer able to speak or swallow. The saliva was wiped from the mouth by the attendant, or she made an awkward and ineffectual effort to do it herself, showing that she was probably not entirely unconscious. Her urine was passed involuntarily. No morphia had been required during the last few days. The neck remained in about the same condition that it was on September 23d. The muscles of the left side of the face were paralyzed, the mouth being drawn well over to the right side.

She died, exhausted, November 13, 1881, at 12.30 P.M.

Post-mortem examination, three hours after death, by Drs. Mills, Bissey, and myself.

Brain.—The venous sinuses and arteries were carefully examined, but were found to present nothing abnormal. No lesion of the membranes was discovered. The pia mater was unusually transparent (almost bloodless). The optic nerves were normal in appearance, and no perceptible lesion was detected in the other cranial nerves. No effusion. Entire surface of brain examined through the transparent pia mater before its removal, and no pathological condition was discoverable. On stripping the pia mater from the right hemisphere, the external surface of the convolutions was still found to be intact. Before completing the process of removal of the pia mater from the right hemisphere a large quantity of a dirty grayish-white liquid suddenly escaped through a small opening at the bottom of a secondary fissure just in front of the upper extremity of the fissure of Rolando.

The right lateral ventricle was laid open by an incision through the lateral border of the corpus callosum. The surfaces of the intra-ventricular ganglia were healthy in appearance. The floors and roofs of the cornua showed no lesion. A longitudinal incision was made through the middle of the head of the caudate nucleus and the optic thalamus, deep enough to pass through these bodies and the lenticular body, just to the inner margin of the insular and sphenoidal cortical substance (gray matter). This incision exposed a small isolated abscess about one inch in length, three-quarters in depth, and one-third of an inch in width, involving the following parts from before backwards; the anterior two-fifths of the lenticular nucleus, and the adjoining portions of the external capsule and claustrum. The caudate nucleus, optic thalamus, and the entire internal capsule were not changed in appearance. The posterior three-fifths of the lenticular nucleus and a very narrow strip of its anterior two-fifths above the abscess were intact. Vertico-transverse sections through the pre-frontal and occipital regions showed no lesions. Further transverse sections revealed a nodulated mass and large abscess of the centrum ovale of the postero-frontal and parietal lobes.

The nodule was about the size of a large hickory-nut. It involved the white matter and the under portion of gray matter at a point corresponding externally to the superior parietal lobule or convolution, a little anterior to the middle of the inter-parietal fissure. Its anterior extremity just grazed the middle portion of the gray matter of the ascending parietal convolution. The nodule was apparently firm. The abscess extended on all sides of the irregular body, and the exact limits of the former were determined by transverse sections to be as follows: Its anterior extremity reached a point in the centrum ovale corresponding to a plane, just in front of the caudate and lenticular bodies, externally through the anterior halves of the first, second, and third frontal convolutions. Its posterior extremity reached a point in the centrum ovale of the parietal near the plane of the parieto-occipital fissure. The abscess in its anterior half involved white matter only, but close up to the gray substance. Its posterior portion involved the white matter, also the inner part of the gray substance of the adjoining convolutions. The posterior one-fourth of the abscess involved the gray matter to the greatest extent, and approached near the surface at the most posterior part. It had, therefore, destroyed the centrum ovale directly in relation with, *a*, the posterior parts of the first and second frontal convolutions; *b*, the middle regions of the ascending frontal and ascending parietal convolutions; *c*, the middle and lower portions of the superior parietal convolutions; *d*, the upper portion of the inferior parietal convolution. The gray matter destroyed was chiefly in the anterior parietal convolution and the superior parietal lobule. The entire length of the abscess was between four and five inches.

The left hemisphere showed no pathological lesions.

Thorax.—Heart and large vessels were normal in appearance. The apex of the left lung contained four cancerous nodules, varying in size from that of a lima bean to a horse-chestnut. The apex of the right lung was the seat of a nodule about the size of a hickory-nut. The middle and lower portions of the lungs were anæmic. The pleuræ were normal, except at the apices of the lungs, where slight adhesions were

formed over the nodular growths. Slight effusion in the left pleural cavity.

Abdomen.—The uterus, ovaries, and ligaments of the womb were the seat of fourteen cancerous nodules, most of which were not larger than a hickory-nut. The liver, spleen, kidneys, and pancreas were anæmic, but free from cancerous growths. The stomach was empty, pale, and contracted, but no induration of its walls was discovered. The upper and lower bowels contained a slight amount of fecal matter scattered throughout their entire extent. The contents of the bowels were soft. No evidence of intestinal obstruction could be detected. The rectum was empty.

Microscopical Appearances.—The nodule in the brain was composed of bloodvessels, brain-substance, extravasated blood, and blood-pigment. No cells of a suspicious character were seen.

Remarks.—The abscesses cannot be attributed to the presence of a cerebral tumor. The history of the removal of a malignant growth from the left breast one year before, naturally suggested to me the probability of a similar one in the brain. No local interference with the venous or arterial circulation of the brain was detected at the autopsy. As causative agents, apparently nothing beyond a profound lowering of the vital forces and the blood infection attendant upon the presence in the system of several cancerous masses were found. If in these lies a sufficient cause, I am at a loss to know why abscess of the brain is so infrequently found in connection with cancer of other portions of the body, or why it is not more generally associated with general anæmia.

Remittent respiration is referred to by Hughlings Jackson (Reynolds' *System of Medicine*), although he does not give it that name, and Cheyne-Stokes' respiration by nearly every recent author on nervous diseases, but I find no allusion to the peculiar intermittent variety found in this case, in which three or four respiratory movements of equal length and depth were followed by distinct intermissions varying in length from fifteen to eighteen seconds.

Just before the patient's death, when the respiration approached the Cheyne-Stokes' character, there was no period or interval of several seconds duration during which the respiration intermitted, but the movements were continued regularly, increasing or lessening as the efforts at respiration reached the maximum or minimum.

One or more cases with respirations differing from the Cheyne-Stokes' similarly to this may be found described in a joint paper presented at the Northern Medical Society of Philadelphia, by Drs. Mills and Ott. (*Phila. Med. and Surg. Reporter*, July 2, 1881.)

The abdominal respiration noted in the clinical history may be imitated by any one in health by first voluntarily expanding the abdomen, then allowing the chest to be inflated subsequently, the expiratory movements taking place in the order of time in which the inspiratory were effected. It differs from the form of abdominal breathing referred to by Hughlings Jackson in connection with cerebral hemorrhage. It is a grave omen, and is most commonly found in cases of great prostration, as in typhoid fever and shock, or it is associated with certain brain diseases attended by a similar condition of the vital forces.

The inflammatory changes that occurred in the right eye and ear, with the subsequent loss of vision and hearing in these organs, cannot be accounted for by any appreciable lesion in the pons, medulla, or at the base of the brain adjacent to the optic nerve. The well-known experiments of Waller, Bernard, and Brown-Séquard, on the effects of stimulation and paralysis of the cervical ganglia of the sympathetic nerve aid us in attributing the trophic changes found in the eye to the local trouble present in the right side of the neck, which preceded the affection of the organs of the special senses. I regret that we failed to examine the indurated tissues of the neck, and to ascertain the condition of the sympathetic nerve and ganglia in this region.

The general cerebral and thermometric records of this case present some points of interest.

General Thermometry.—According to the physiological experiments of Hitzig, Eulenberg, and Landois (quoted by Mills, *Phila. Med. Times* for January 18, 1879), the heat-controlling centres are situated in the cerebral cortex of the motor regions around the fissures of Rolando, especially in the ascending convolutions. Usually, but not constantly, destruction of this area gave rise to increased, and irritation produced lessened, temperature in the extremities of the opposite side of the body. In the present instance the large abscess involved to some extent the supposed thermic area of the right side. Comparative observations of each axillary temperature were made on seven different occasions, and were as follows:

	Right Axilla.	Left Axilla.
September 8,		99°
" 12,	96°	99.4°
" 13,	97.9°	98.4°
" 14,	97.9°	98.2°
" 19,	97°	98°
" 22,	97.6°	98.2°
" 23,	98.9°	98.2°
November 11,	95.5°	98.2°

The temperature of the right or non-paralyzed side of the body only once exceeded that of the left, when the thermometer registered .7° higher in the right than in the left axilla. The temperature of the left armpit ranged from .5° to 3° higher than that of the right. During the first shock to the system, produced by the abscess, and just before death, when paralysis was most complete, the difference between the two sides of the body heat was greatest, being 3.4° at one time, and about 3° at another.

Cerebral Thermometry.—I shall only refer to the extended observations of Broca, Gray, and Maragliano, and Sepelli, on cerebral thermometry in health and disease. Their conclusions are in harmony with each other, and their utility has been demonstrated by observations made on at least two cases of tumor of the brain, one by Dr. Charles K. Mills (*Phila. Med. Times*, Jan. 18, 1879), and the other by Dr. Landon Carter Gray (Hamilton's work on *Nervous Diseases*, 2d ed., page 22), who was the first in this country to investigate the surface temperature of the head in health. Dr. Gray found the average normal temperatures of the stations on the left side of the head to be for the frontal, .65°; for the parietal, .85°; for the occipital, .72°, higher than those of the corresponding stations on the right side. He gave as the average normal temperature of the right frontal station, 93.71°; of the left, 94.36°; of the right parietal, 93.59°; of the left, 94.44°; of the right occipital, 91.94°; of the left, 92.66°. Variations of more than 1.5° he considered suspicious of disease at that point, and of more than 2° strong evidence of a pathological condition.

Comparing the results of the surface temperatures of the head made on the case reported at length in this paper with those reported by Gray and others, we shall find several points of difference. The temperatures were from 2° to 4° higher than those obtained on the heads of healthy subjects, although the axillary temperatures of this case, taken at the same time, were normal or subnormal. The temperatures at the several stations on the left side of the head exceeded those on the right by about .5°, which is nearly in accord with

the normal difference. The temperature at the left Rolandic station was .2° lower than that of the right on one occasion only. With this exception, the temperatures on the left side were the highest. On September 23, when paralysis of the left side of the body was complete, the surface heat at the left posterior frontal station was 2°, and at the left parietal 1.5° greater than at the corresponding stations on the right side. Before complete paralysis had taken place in the left leg, there was nearly an equal increase of heat at the frontal and posterior stations; later, when the leg was powerless, the temperatures of the posterior stations exceeded their normal more than did those of the anterior. In the observations on cerebral thermometry in connection with brain tumors made by Drs. Mills and Gray, the stations nearest the growths, both of which happened to be on the right side, gave the highest average increase of temperature.

The area to which the occluded vessels in embolic hemiplegia are distributed is said to have a subnormal temperature.

I am not aware that the results of any observations of the surface temperature of the head made on persons suffering from abscess of the brain have been reported. No valuable conclusions can be drawn from observations made on a single case; especially is this so when the surface temperatures of the head are not more frequently taken than in the history of the one just reported. In health, the head temperatures are from 4° to 6° lower than that of the axilla, being lowest posteriorly. In the present case, with a normal or subnormal axillary temperature, the head temperatures were elevated from 4° to 6° above their normal, the occipital, in one instance, being the highest, equalling the axillary, and exceeding its own in health 6°.

Dr. Allan McLane Hamilton, of New York, has reported the results of his observations on a case of meningitis, in which the occipital temperatures exceeded those of the other regions of the head. (*Ibid.*)

It is doubtful whether the local temperatures of the head in abscess of the brain will aid us in locating the disease to any particular region, but if the results of the observations already made on cerebral thermometry in brain tumor be sustained by future investigations, the surface thermometer may help us in differentiating abscess from tumor of the brain.

In a case of brain trouble, in which the diagnosis is between tumor and abscess, a limited surface area of one side (especially the right) of the head with a temperature considerably elevated above the heat of the surrounding parts, would point to tumor; whereas, an elevation of the entire cerebral surface temperature would indicate abscess.

The direction of the destructive lesion in the brain, if we may judge by the progress of the paralysis, was from before backward, showing that the nodule occupied the region last involved, instead of the first, as would have been the case if it had been caused by an embolus, and had in its turn given rise to the abscess.

CASE II. *Abscess of the brain following chronic meningitis: sudden death.*—On the notes of Dr. Dennis the history of the following case is based:

Mr. G. S., æt. 56, shoemaker, served in the German army, and when a young man led an irregular life. He presented no marks of syphilis, and no history of his having suffered from that disease could be ascertained. He had always been a moderate drinker of beer, but never indulged in the stronger alcoholic liquors. He was a large, heavily built man, and, with the exception of occasional headaches, had enjoyed good health until the latter part of the year 1880, when the loss of his wife, followed by other domestic unhappiness, seemed sufficient to disarrange an already ill-arranged nervous system. His temper had been irritable for many years, but now he became subject to frequent outbursts of passion, during which he would vent his spleen on any one who chanced to be near him. His memory became very treacherous, often getting confused in his business, and even at times being unable to remember the day of the week. His headache became constant and more severe.

During the spring and early part of the summer of 1881, he had what he called "rheumatic attacks," during which, while attending to his usual duties, he would be seized suddenly by a sharp pain in the course of the left sciatic nerve, followed by immediate paralysis of the left arm and leg, compelling him to sit down to save himself from falling. During the attacks he did not lose consciousness. The paralysis never lasted longer than a few minutes, power of motion returning and seeming to be as good as before the shock. The frequency of the hemiplegic seizures, two or three attacks often occurring weekly, depended upon causes giving rise to outbursts of passion. Sudden changes of weather were apparently associated with the nervous disturbance.

His symptoms remained unchanged until the latter part of October, when, in a fit of anger, he fell to the floor, frothed at the mouth, and became convulsed. No paralysis followed the convulsion, but the headache steadily increased, compelling him to take to his bed. As on this, so on every succeeding, day during his entire illness, he remained in bed only a portion of the day. The head-pain now constant was so severe that it prevented continuous sleep, and from short naps which he would occasionally get, he would be awakened suddenly by violent exacerbations of pain. Two weeks before his death, Dr. Dennis was requested to take charge of the case. His temperature at this time was 99.5°; pulse 70 per minute, full and strong; respirations natural; appetite capricious, tongue coated, stomach intolerant, and bowels obstinately constipated. Urine scanty, high colored, and free from albumen, was voided voluntarily until a short time before his death, when it was occasionally passed involuntarily. The skin was slightly jaundiced. He complained of occasional chills, and was very sensitive to changes in the atmosphere. Nocturnal delirium soon began. He was very restless, saw strange things and people in his room, and would occasionally rise during the middle of the night and awake the whole family, telling them that it was time to get up for the day. At times his mind seemed to be a blank, he could not tell the day of the week, and would frequently be unable to distinguish day from night. On other occasions his mind was clear, but during these lucid intervals he could converse intelligently and connectedly for a few minutes only, thought ceasing to be generated, when a vacant stare would be his only reply to questions which a few minutes before he had answered promptly and correctly. Impressions were persistently and obstinately adhered to, and any attempt at persuasion to the contrary was not calmly received. His headache, principally frontal and right-sided, was now sharp and lancinating, requiring hypodermic injections of morphia and atropia to relieve it. The orbital and other branches of the fifth nerves were very sensitive to pressure. His temperature during Dr. Dennis's attendance, though usually above the normal, reached 100° Fahr. only on two or three occasions. The muscles of the left arm and leg were decidedly weaker than those of the right, yet sufficiently strong in the leg to support his weight for a short time. Turning in bed was difficult. When the left arm unaided was held at right angles with the body a decided muscular twitching began. Occasional muscular twitchings took place when the arm was passive. He thus continued, gradually getting worse, until November 25th, about five

weeks after his giving up work, when Dr. Dennis requested me to see him in consultation.

When I first entered the room he seemed bright, and conversed intelligently. He had not talked long, however, before he began to hesitate in his answers, appearing to have difficulty in understanding me, and being more puzzled in framing answers to my questions. Soon he was unable to form more than one or two words of a sentence, and finally uttered a meaningless "yes" or "no," or stared vacantly, when spoken to. Pupils were small and equal in size, brows were contracted, and he complained of great pain in his head. The eyes were very sensitive to light, making it extremely difficult to make an accurate or satisfactory ophthalmoscopic examination. The acuteness of vision and the condition of the other special senses could not be ascertained. The retinæ were found to be slightly hyperæmic, and the optic disks somewhat swollen. No muscle or groups of muscles were paralyzed, but those of the left arm and leg were weak, and an attempt at coördination produced a muscular tremor. The left side of the face was apparently less expressive than the right. The heart, lungs, liver, and kidneys showed no evidence of disease. Temperature was 100°; pulse 68, and full; respirations 16 per minute. An opinion was given that the man was suffering from chronic meningitis of several months' duration, and that a recent complication of softening or abscess of the brain had taken place.

The next day Mr. S. was feeling so comfortable that he got up, dressed himself, and without assistance went down stairs from the third to the first floor to dinner. After eating he was helped to his third-story room. He expressed himself as feeling tired and sleepy, and lay down to rest. He was left alone about one hour, when one of his daughters looking in his room found him on the floor, where he had fallen in getting out of bed. The left side was now found to be entirely paralyzed. He was placed in bed and left alone. Shortly after this, when looked after, he was found asleep and snoring loudly. As his repose was supposed to be a natural one, he was not immediately disturbed. About 6 P.M. the daughter, thinking it strange that nothing was heard from her father, went into his room and endeavored to arouse him, but to her surprise found him dead.

Post-mortem examination thirty-six hours after death.

Brain.—The dura mater over the entire extent of its bony attachment, was inflamed and firmly adherent to its osseous envelope. At the base of the brain the external membrane was so closely attached that it could be separated from the bone only in piecemeal by the scalpel. The cranial nerves were apparently uninvolved in the diseased process. No abnormal quantities of fluid were found in the subarachnoid space. The bloodvessels of the pia mater were engorged, and the membrane was slightly adherent to the brain substance. The entire external surface of the brain appeared nearly normal, presenting no gross lesions of softening. Superficial portions of convolutions in the neighborhood of the greatest amount of inflammation were examined under the microscope, and found to be in nearly a normal condition.

An abscess was found on the right side involving chiefly the centrum ovale of the pre-frontal region, but also to some extent, in its middle part, the inner layers of gray matter of the first, second, and third frontal convolutions. On attempting to localize exactly the posterior limits of the abscess, it was found that a vertico-transverse section through the anterior lobe made just in front of the pre-central fissure externally, and striking the anterior extremities of the ganglia internally, just grazed its posterior limits. The abscess extended forward to within one inch of the anterior extremity of the lobe. Very few, if any, of the white fibres from the ascending frontal convolutions were involved. At the posterior and interior boundaries of the abscess a bloody nodulated mass two-thirds of an inch in its greatest dimensions was found. Other portions of the brain were apparently healthy. No emboli or thrombi were found.

The abscess did not communicate with the lateral ventricle, nor open upon the external surface of the brain to account for sudden death.

Microscopic examination of the nodulated mass and adjacent parts showed no new cell formation tissue; the nodule and the parts around exhibited nothing besides disintegrating brain tissue with its bloodvessels, and a few blood corpuscles.

Remarks.—We cannot boast of our knowledge of the functions of the antero-frontal lobes, yet pathology, and later, physiology, have from time to time thrown some light on this obscure subject. The "crow-bar case" of Bigelow, the bullet wound related by Trousseau (quoted by Ferrier), the other cases mentioned, analyzed by Charcot and Pitres (reviewed by Ferrier, and quoted by Mills, *Phila. Med. Times*, Jan. 18, 1879), the tumor of the right antero-frontal lobe presented to the Pathological Society of Philadelphia, by Dr. C. K. Mills (*Transactions of Phila. Pathological Society*, vol. ix. page 106), and the lesion just described in connection with Case II. of this paper, in all of which the antero-frontal lobe was destroyed to a greater or less extent without any paralysis attributable to the lesion in this region, lead us to accept the conclusions of Charcot and Pitres, that motor disturbances of the slighest character do not necessarily follow lesions in the antero-frontal regions.

For the light physiology has shed upon the function of this region of the brain, I quote from Dr. Mills' article on tumor of the brain (*Phila. Med. Times*, Jan. 18, 1879): "Ferrier, *Functions of the Brain*, p. 230, in his experiments on the antero-frontal regions of the brain of the monkey, generally obtained negative results. Electrical irritation usually caused no special manifestations. Removal or destruction was not followed by any definite physiological results. The animals operated on, however, while not actually deprived of intelligence, had apparently lost the faculty of attentive and intelligent observations. When considering the hemispheres physiologically, Ferrier argues also that the power of fixing the attention and concentrating consciousness depends on inhibition. He shows that if the centres of inhibition, and thereby the faculty of attention, are weak, or present impulses unusually strong, volition becomes impulsive rather than deliberate."

It will be remembered that the patient in Case II., where the lesion was in the antero-frontal lobe, presented symptoms in accord mainly with the physiological experiments of Ferrier. The man was emotional and passionate, and his power of attention was weak and of short duration. He seemed at times to lose will power. Only temporary paralysis was observed, and this always after some fatigue, which may have induced some restraining influence from other portions of the brain, or what is probably more correct, as some of the fibres connecting the motor region of the brain with the muscles of the arm and leg were destroyed, the remaining healthy fibres became exhausted from overwork.

Among the other interesting features of the second case are, the sudden death and the patient's ability at times to walk well, although at others the paralysis was so extensive that he was not able to stand.

That he was able to walk at all was apparently due to the fact, sustained by the post-mortem examination, that not all of the fibres through which motor impulses

passed from the brain to the muscles of the leg were involved in the destructive process. When he was resting, a few fibres, for a short time, could do the work of a greater number.

If this view be correct, it will enable us to explain the cause of sudden death, although there was neither hemorrhagic apoplexy, nor bursting of the abscess into the ventricles, or on the surface of the brain. The unusual strain that he put upon his crippled brain a few hours before his death, in descending and ascending two flights of stairs, and in sitting up to eat his dinner, so exhausted his nerve centres that its effects came like a shock from a severe cerebral hemorrhage. The occurrence of the hemiplegic seizures may be accounted for, probably, by the sudden overloading of the congested vessels of the brain during his fits of anger.

CASE III.—*Abscess of the brain; gangrenous inflammation of the right Sylvian artery, and occlusion of some of its branches; facial erysipelas; pneumonia in the left lung.*

J. R., male, aged about forty, laborer in a sugar refinery, had been sick and delirious for several days, was brought into the St. Mary's Hospital during the past winter, in an unconscious condition. His previous history could not be ascertained. His respirations were rapid and abdominal; pulse small, weak, and irregular; temperature not taken. No urine was obtained for examination. His face was swollen and of a dark erysipelatous hue. The swelling around the eyes was too great to admit of an examination of the pupils. The facial swelling and comatose condition prevented the detection of local palsies, if such existed. He did not regain consciousness, but died about six hours after his admission.

Autopsy eight hours after death.—The abdominal cavity was not opened. The entire left lung was in the second stage of pneumonia; the right lung and the heart were in nearly normal conditions. Only slight quantities of serous fluid were found in the pericardium and right pleural sac; considerable fibro-serous effusion was found in the left pleura.

Brain.—The dura mater was slightly congested, but there were no evidences of decided inflammation in it. The pia mater covering the convex surfaces of both hemispheres, and that beneath the right, was opaque. Its bloodvessels were highly engorged, and deposits of lymph and pus were found. At and just posterior to the right Sylvian fissure there was a considerable quantity of pus, and sufficient lymph to so mask the structures at this point as to make them look like one mass of inflammatory products. The trunk of the Sylvian artery was almost black, its calibre lessened, but apparently not entirely obliterated. Some of its secondary branches, especially the lower ones from the parieto-sphenoidal and sphenoidal arteries were occluded and seemingly gangrenous. After carefully removing the pia mater, the convolutions and brain substance of the left hemisphere appeared nearly normal. The under and external surfaces of the right temporo-sphenoidal lobe, from its anterior tip to its junction with the occipito-parietal lobules, were softened to the depth of about an eighth of an inch. A superficial abscess or a mass of softened brain substance, about one inch in all its dimensions, occupied the anterior extremities of the first, second, and third temporo-sphenoidal lobules. The contents of the abscess were, in the centre, a watery fluid, surrounded by broken-down brain substance and blood constituents, and, on the outside, a thick layer of pus and other exudative matter. The cranial nerves were but little encroached upon by the inflammatory deposits. Nothing special was noticed in the sinuses of the brain besides their blackened and engorged appearance. The ganglia were apparently normal.

The patient was under observation only six hours before his death. The circumstance of his death was investigated by the coroner, which necessitated great hurry in examining the brain and its membranes and sinuses.

DR. CHARLES K. MILLS said: A careful examination of the cerebral sinuses might have thrown some additional light upon the third case. It was of great importance in all cases of abscess of the brain to investigate the condition of the sinuses of the dura mater. Abscess and thrombosis were not infrequently associated, and sometimes held to each other a causative relation. In the account of the condition of the patient (Case III.) it was stated that his face was swollen, and of a dark erysipelatous hue, the swelling around the eyes being too great to admit of an examination of the pupils or of the interior of the eyes. The erysipelatous appearance may have been the pseudo-erysipelas which accompanies some forms of cerebral thrombosis. The ophthalmic veins end in the cavernous sinuses. These veins have also a communication with the veins of the face. The facial vein, beginning on the anterior portion of the head, descends about the middle of the forehead, as the frontal vein, to the root of the nose, and then is continued downwards around the angle of the eye, under the name of the angular vein. This angular vein communicates with the ophthalmic vein. Hence it will be seen how swelling of those veins outside of the skull, which inosculate with the sinuses within, may become the most striking and positive signs of obstruction of the sinuses. Œdema of the eyelids and face, and congestion of the eyes, mean venous stasis in the parts drained by the ophthalmic veins. These phenomena were present in Dr. Eskridge's third case.

These three cases of abscess of the brain, well studied and described, constitute a valuable addition to the literature of intra-cranial diseases.

CORRESPONDENCE.

LETTER FROM BERLIN.

The Gesundheits-Amt; its Workers and its Work.

NUMBER 57 Louisen Strasse is a plain, substantial building, not differing in the least from ten thousand other plastered bricks in this city, and found by the stranger only by special direction to it. It is in fact an ordinary house, rented and used by the Gesundheits-Amt or Health Office of the State—a creation of Bismarck's within the last two years. Yet in this unpretentious building was worked and from it was published the discovery which marks an epoch in the history of our science; to wit, the parasite of tubercle by Dr. Robert Koch.

When a year ago Dr. Finckelnberg was called away to take a higher place, no name seemed so prominent in this field among the younger workers of the land as that of Dr. Koch, then in practice at Wollstein, a little town about midway between Breslau and Berlin. He had already made a reputation in Parasiten-Kunde by his work upon milzbrand and the surgical infections, but it was confined chiefly to among his associates in this particular field of work. It seemed, however, to Dr. Struck—Ober-Geheimer Medizinal Rath is his justly earned title—the present Director of the Health Office, that Dr. Koch was the man for the place, and accordingly hither he was called to take his place as a Regierungs Rath among several other workers in the field of hygiene or public sanitation. How fit the selection was has just been proven by the publication of the discovery of the parasite of tubercle, which

implies the unveiling, we might say, of the greatest mystery of our age.

The Gesundheits-Amt here differs in its methods of work as widely as in its construction and arrangement from any ordinary health office in our country. Many poisons find their way into it, and many are discovered in it, but the poison of politics never pollutes its walls. Whether the Liberal or Conservative is triumphant, it will have no effect upon the occupants of this place. Hence appointments are permanent and are salaried, too lightly it is true, but nevertheless at such a rate as to relieve its employés, if such a term is proper, from the vulgar struggle for subsistence. Hence, too, its work is purely scientific, and the publications regularly issued from it rank at once as authoritative upon the subjects they discuss. The various rooms in the house are differently occupied by chemists, pathologists, etc., each having his own set of compartments and assistants. Just across the street is the Charité, whence to derive any kind of material for examination, and adjoining on the south is the large veterinary college with a full corps of teachers to supply material of its kind.

Dr. Koch's apartments proper consist of a suite of connecting rooms, a kind of flat, as it were, in which there are at present five workers besides himself. These workers are representatives, or, I might say, delegates, from different departments of the house or from foreign governments. For instance, there is one here now from the Saxon, one from the Hungarian government, and one from the German marine service. Each one, like Dr. Koch, has his own desk, separated from the rest by projections of shelves and drawers, as in a well-filled library, covered and filled with specimens and tools. Perhaps the most striking furniture of the rooms is the array of test tubes; by the hundred they are here, each partly filled with sterilized substances, gelatine or blood, and each stopped with a plug of cotton which has become brown in the process of sterilization. The tubes contain the parasites of many known and described, and many as yet undescribed, diseases of animals, growing in the culture substance, and abstracted daily for inoculative experiments, or for further cultivation in fresh material. These tubes crowd the shelves and stands in every direction, but never in the least confusion, as each is distinctly labelled as to contents and date of preparation.

In the centre of each worker's compartment, at a window, of course, stands, with all its appurtenances, a first-class microscope, mostly of the manufacture of Zeiss, of Jena, one only of Hartnack, of Potsdam, who has only now perfected his instrument with the oil immersion lens and Abbè illumination apparatus, necessary factors for this kind of work. A first-class instrument of this class costs here, I may add in a parenthesis, $125 to $150, Hartnack's being now just as good as Zeiss's, and a little cheaper. This instrument so arranged is a *sine quâ non*. Without it, it is not impossible, it is true, but it is not easy to define the bacilli of tubercle when but few are in the field.

These delegates, by the way, are not students of medicine in the ordinary sense of the word, nor are they practitioners, but men of science, all of medical science, of course, who expect to devote their lives to this kind of work. A mere association with this class of men is an education of itself, for it is the pure school of observation. Nothing whatever is taken for granted; nothing is inferred or deduced or reasoned out or speculated upon. Everything is simply examined and described. Dr. Koch is the referee in questions of doubt, and, so far as I have been able to see, he can determine any ordinary matter of doubt at a glance. For instance, two of us worked in vain a whole day over the tubercle parasites in a specimen of sputum, and finally in despair called him in. He noticed at once that the shade of one of the color tests was not correct, and at once declared that we had used an alcoholic instead of an aqueous solution, which was true, and which was the cause of failure. Of course there is nothing new or strange in this quick detection of the source of error, as it is the natural consequence of the study of years, of one, at least, with the same or similar reagents.

Work commences in the laboratory at 9 A. M., adjourns at 3 P. M. for dinner, is then resumed to continue until 5. But on Sunday the work ceases about noon. The Director of the office makes a general assignment of the work, but each man is left pretty much to himself. So one man will be found engaged with tuberculosis, another with milzbrand, a third with the organs of some animal which has died at the veterinary stables, another with the analysis (not chemical, for this takes place elsewhere, but mycological) of drinking water, or of soil, perhaps, sent in from elsewhere, etc. To-day there is an interruption, as Drs. Koch and Gravitz have been sent to Wittemberg to study the etiology of an epidemic of typhoid fever which is just announced, but the work by the rest goes on just the same.

Just how this work is done, and with what result, I propose to write again. Only this much I ought to say now regarding the bacillus tuberculosis, namely, that it is a fixed fact, and is capable of the most complete and convincing demonstration. Dr. Koch was called before the Emperor, just before his departure to Ems, and I have it, from outside parties, that the deepest interest was shown in the demonstrations.

J. T. W.

BERLIN, June 25, 1882.

LETTER FROM CANTON.

Medical Progress in China.

THE Sleep of Ages rests upon the doctors of China. How deep that sleep is can be imagined if one will go back to the dark ages of Europe, when superstitious ignorance controlled the administration of medicines. Accustomed to regard the Chinese as an inferior race, we may not wonder that they are satisfied with the crude notions of their ancestors of a hundred generations back.

But it is a question yet to be decided whether they are the inferior race. In literature, the arts, and commerce, they take the lead of all the nations of the East, and in diplomacy their statesmen have shown themselves a match for the best men they have met from Europe and America.

Moreover, a few thousands of ignorant peasants have gone to Australia and California, taken up the industries of the people, and in a quarter of a century have monopolized some of the most important trades and occupations. Not only so, but the statesmen of the two great Anglo-Saxon nations have been driven to their wits' end to devise means by which to protect the so-called superior race from the encroachments of these heathen peasants. The recent measure adopted by Congress will only add to the confusion of California's Senators and Representatives. Thus far, against all disadvantages, the illiterate Chinaman has the best of it, and will continue to hold his ground as long as he is a sober, reliable, industrious, painstaking workman, and his competitors waste their money, strength, and character in the drinking saloons.

Hitherto it has been for the most part peasants who have come in competition with the laborers of foreign countries; but other classes are slowly coming forward. Chinese merchants are beginning to adopt foreign modes of doing business. Steamships and insurance companies are established by them, and the advan-

tages of the telegraph are not neglected. The professions of law and medicine have their representatives, and it is among the possibilities of the future that members of these professions in Europe and America may have for competitors enterprising Celestials who, imitating their more illiterate countrymen, shall push their way into those countries where they will find more activity, more life, and more dollars.

There is now in Hong Kong a Chinese who practices in H. M. Courts, and another has just returned to that colony from England who has taken degrees in both law and medicine, and is qualified, under English law, to practice either profession or both, as he pleases. For a number of years the position of physician to the European community in this city was held by a Chinaman, the late Dr. Wong Fun, who took his degree in Edinburgh.

The question as to which is the superior race cannot be finally decided until the educated classes of China have adopted our professions, and stood in competition with our best men in the great arena of life.

In view of the national and individual characteristics of the people, we cannot but wonder that the healing art should have remained very much as it was ages ago. Experimental medicine has nowhere had such vast opportunities. During all these centuries innumerable doctors, having untold millions of willing patients, have administered to them all the medicines which the three kingdoms of nature could furnish. We cannot cease to wonder that empirical medicine, under such circumstances, has so little to offer to the world, as valuable additions to our means of combating the diseases common to the human race.

The explanation is not difficult to find. Among all their wise men and sages, they have had no Bacon or Locke to teach them the true mode of investigation. With blind reverence for antiquity, the *very multitudes* of the people have destroyed individuality of character, and fixed custom in medicine as an unchangeable law which no one was strong enough to set aside. Of course without anatomy and physiology it was impossible to have anything like a scientific system. And the native faculty have yet to make a beginning in these departments.

While the sleep of ages still rests undisturbed upon the great mass of the doctors of the Empire, the people are beginning to be aroused by the influences brought to bear on them by contact with Western nations.

The translation of medical books has placed within the reach of scholars the outlines of the several branches of study in the medical course.

The military and civil hospitals established by the English and French in such places as Hong Kong and Shanghai, and the missionary hospitals in successful operation in more than a dozen cities of the Empire, have presented to the people the advantages of treatment as practised in these institutions.

The attempt has been made to imitate these institutions, and they have spent money liberally in erecting buildings in Hong Kong and Canton, but beyond the practice of vaccination there is no disposition to give up native practice or adopt foreign.

A few young men have acquired a knowledge of Western medicine and surgery, and some of these have made reputations which gave them a high standing. The first and most prominent of these was Kwan Ato, a pupil of Dr. Peter Parker, the founder of medical missions in the East. He died some years ago, in this city, leaving quite a fortune acquired by his practice. He was the first, and for many years the only, Chinese who ventured to perform surgical operations. In ordinary cases, requiring little anatomical knowledge, he was a skilful surgeon, and he did much to recommend Western surgery and medicine to the people.

There are many others who have acquired considerable practical knowledge of medicine and surgery in the various missionary hospitals now in operation, and there will be a regular increase in their numbers as better facilities for their instruction are placed before them in medical schools, equipped with qualified instructors, suitable apparatus and text-books up to the recent advancement of the various departments. It is the day of small things with my medical class of a dozen pupils in a city of one million inhabitants, but some of my successors may stand before classes as large as any now seen in the cities of Europe or America.

J. G. K.

CANTON, CHINA, May, 1882.

MEDICAL EDUCATION IN OHIO.

To the Editor of THE MEDICAL NEWS.

SIR: I desire to present the position of the Columbus Medical College, in relation to the charges made against the said College by Dr. James E. Reeves in his address before the West Virginia State Medical Society. This I am impelled to do by an editorial notice in your journal of July 8, 1882.

In January, 1882, A. M. Dent, of Weston, West Virginia, applied for admission into the Columbus Medical College as a candidate for graduation. He stated he had just been rejected on his examination before the State Board of Health in West Virginia, and that this rejection would destroy his practice, and be ruinous to him. He was informed that but five or six weeks of lectures would be given before the close of the term, and that no concession in his behalf could be made in the matter of examination, and if he became a candidate he would be obliged to pass the same examinations in all branches which the other members of the class submitted to in order to receive their diplomas.

He said all he asked was the privilege of making the attempt, and if, during the remainder of the term, he could not, by hard study, pass the examination, if rejected, he would make no complaint; all he desired was to be placed on the same ground as the rest of the class.

A. M. Dent had attended a course of lectures in 1874 or thereabouts in Starling Medical College while three of the present members of the faculty of Columbus Medical College held chairs in that College, and he exhibited the tickets of the College in evidence thereof. He presented his certificate of membership of the West Virginia State Medical Society. Before he could become a member, being a non-graduate in medicine, he was examined as to his fitness for membership of said Medical Society by the Censors of the Society, and by them recommended and was elected.

In 1879, he presented a paper before the West Virginia State Medical Society, which may be found in the Transactions of said Society for that year.

He presented the certificate of the West Virginia State Medical Society, showing that he had been elected or appointed a delegate from the said Medical Society to represent it in the American Medical Association, which met in 1881 at Richmond.

He had also during the same year been appointed one of the Trustees of the West Virginia Lunatic Asylum by the Governor of the State.

He brought the certificate of two prominent and reputable physicians of West Virginia, testifying to his regular professional standing, his general reputation as a physician, and good social position in the community in which he lived.

In view of all the above-mentioned circumstances, he was admitted to the College as a candidate for graduation. At the close of the term he was examined with the rest of the class, orally by some chairs, in writing by others.

In practice of medicine, 100 being perfect, his grade was 75, in therapeutics 80, in obstetrics 90, in surgery "very good." His grades in anatomy and physiology I cannot give. The course in chemistry had closed when he entered the school; whether the professor in this department examined him or not, I do not know.

The Professor of Surgery was a member of the State Board of Examiners who passed upon the qualifications of the regimental surgeons of Ohio, during the late war. He says of hundreds of papers he then examined, the average was no better than Dent's final examination for the degree.

Under these circumstances the Faculty of Columbus Medical College believed they were justified in granting A. M. Dent a diploma, nor do they believe they have done harm to the profession by admitting A. M. Dent to the profession, and its honors and privileges under the diploma of the Columbus Medical College.

As to "short time" in the course of medical lectures, the members of the Faculty are aware that it has been the custom of many colleges in the country to use their discretion in the matter of insisting upon "full time" of attendance upon lectures, when conferring degrees, when good cause could be shown for favor in this direction.

A. M. Dent was not guilty of the anatomical errors mentioned by Dr. Reeves; on this point the certificate of the Professor of Anatomy which Dent has is conclusive. Those making the errors mentioned are unknown to the Faculty, for no such examinations were reported to them. The entire Faculty signed the diplomas; no objections to doing this were made by any member of the Faculty.

Such is the position of the Columbus Medical College in relation to the charges made by Dr. J. E. Reeves. The College has done no intentional wrong. The College will ever insist upon the same standard for the acquisition of its diploma which all other medical colleges in this country deem necessary to secure theirs.

D. N. Kinsman, M.D.,
Dean of Columbus Medical College.

Columbus, O., July 13, 1882.

DR. GEORGE McCLELLAN'S TUBULAR NEEDLE.

To the Editor of The Medical News.

Dear Sir: In your issue of July 15th is figured a tubular needle devised by Dr. George McClellan for the pocket-case. If Dr. McClellan will refer to the *Medical and Surgical Reporter* for September 14, 1878, he will find a newly arranged and very compact pocket-case devised by myself, in which, among other improvements, this identical instrument is introduced. In addition to the uses which he points out, he will find it very useful, as there described, in passing harelip pins, during the withdrawal of the needle.

Very truly yours,
W. W. Keen, M.D.

Philadelphia, July 17, 1882.

NEWS ITEMS.

VIENNA.

(*From our Special Correspondent.*)

Billroth's Festival.—The event of the past week has been the celebration of Billroth's declination of Langenbeck's Chair of Surgery in Berlin. The midday reception was held in the aula of the old University, and was replete with everything that is comprehended under the term of "Teutonic splendor." The Faculty of Medicine and corps of teachers attended in body, and representatives of the other faculties were present. The elder son of Prof. Carl v. Braun Fernwald delivered the address upon the part of the medical students and Faculty of Medicine. The address was strong, but in good taste, and bore the name of Duke Dr. Theodor, of Bavaria, as the first of the undersigned students. Billroth's reply was characteristic in its clearness, conciseness, completeness, and elegance of diction. In one portion of the reply Billroth said, "The highest distinction in my call to Berlin lay in the fact that my beloved master, Langenbeck, to whose eminence I cannot hope to attain, selected me from among all his pupils as his successor. I hold this, in fact, as the highest honor which has formed part of my life, already rich beyond desert in recognitions and distinctions." The torch-light procession in the evening of the same day assumed such gigantic proportions as to resemble the civic processions of mediæval Vienna. "Truly," in the language of a citizen of the Imperial City, "the Billroth Day forms a beautiful page in the history of the Vienna University.

Election of Rector-Magnificus, Vienna University.—The Academic Senate and electors of the four Faculties of the Vienna University assembled during last week to elect the Rector-Magnificus for the coming year. After a perfectly amicable congress, Hofrath Dr. Friederich Maassen was elected Rector-Magnificus of Alma Mater Rudolfina for the academic year of 1882–'83. Dr. Anselm Ricker, the present Rector-Magnificus, will officiate during the same period as pro-rector.

Prof. Henry J. Bigelow's Monograph, "Die Moderne Lithotrite."—Prof. Bigelow's treatise upon "Die Moderne Lithotrite" has been severely and justly criticised in "respect to the German employed," though the merit of the matter of the book is freely acknowledged.

Health in Michigan.—Reports to the State Board of Health, for the week ending July 8, 1882, indicate that diarrhœa and puerperal fever have considerably increased, that diphtheria, cholera morbus, remittent fever, and measles, have increased, and that bronchitis, rheumatism, and cerebro-spinal meningitis have decreased in area of prevalence.

Notwithstanding the increased prevalence of diarrhœa, it is still far below what is usual at this season of the year; and the unusually cool summer is also noticeable for the greatly lessened prevalence of intermittent fever; the per cent. shown in this bulletin being 76, whereas in June and July, 1879 and 1880, over 90 per cent. of the reports received stated its presence.

Including reports by regular observers and by others, small-pox was reported present during the week ending July 8, and since, at 4 places, as follows: at Grand Rapids (one death, July 8, one new case, July 9), at Detroit and at Flint (13 cases), at Lansing (one case), July 12.

American Medical Association.—The Committee of Publication have adopted the following rules, to ensure promptness in the appearance of the forthcoming volume of transactions:

1. All addresses and papers read at the recent meeting of the Association, and referred to the Committee of Publication, must be in the hands of the Permanent Secretary before July 31.

2. The transactions will absolutely go to press August 5, and all papers or addresses entitled to appear in the volume, not received by July 31, cannot be inserted.

3. Under no circumstances will the Committee permit new material, different from that in the original manuscript, to be added to the proof-sheets.

The following provisions of the by-laws of the Association will be strictly enforced:

"Every paper received by this Association and ordered to be published, and all plates or other means of illustration, shall be considered the exclusive property of the Association, and shall be published and sold for the exclusive benefit of the Association."

"Authors of papers are required to return their proofs within two weeks after their reception, otherwise they will be passed over and omitted from the volume."

The New York Code.—The Jefferson, Oneida, Seneca, and Chautauqua County (N. Y.) Medical Societies, at their late meetings, repudiated the State Society's New Code and reaffirmed their allegiance to the National Code. The Clinton County Society has joined the Tompkins County Society in adopting the New Code. The statistics, so far as heard from, stand twenty-eight County Societies against the New Code to two in favor of it.

Introduction and Prevention of the Spread of Contagious Diseases by Immigrants.—The Health Officer of the port of New York has issued the following circular to owners and managers of passenger steamship lines at the port of New York:

The following rules and regulations have been adopted by the National Board of Health and approved by the President of the United States, November 14, 1881:

"1. That all persons coming from or through any foreign port or place in which small-pox exists, who after the 14th day of November, 1881, shall arrive at any port of entry within the United States, shall be subjected to examination as regards to their protection from that disease by the proper health authorities of the State within which such port lies; or in case such authorities shall fail or refuse to enforce this rule, then by some officer or proper person to be designated by the President of the United States.

"2. That in case any person so arriving shall refuse to submit to such examination, or upon undergoing the same, shall be found not sufficiently protected from small-pox, such person, and in case he or she be not *sui juris*, then also the person having him or her under charge, shall be detained in quarantine until he or she shall have been properly vaccinated, or shall have passed the period of incubation from date of last exposure."

Attention is also respectfully called to the following rule and regulation of the National Board of Health:

All merchant ships and vessels sailing from a foreign port where contagious or infectious disease exists, for any port of the United States, must obtain from the consul, vice-consul, or other consular officer of the United States at the port of departure, or from the medical officer, where such officer has been detailed by the President of the United States for that purpose, a bill of health in duplicate, which shall set forth the sanitary history of said vessel, and that it has in all respects complied with these rules and regulations.

Believing that protection of the lives and health of the people demand the adoption of the foregoing rules and regulations, the following requirements will be made of the officers of steamships entering this port:

1. Bills of health will be required by the quarantine officials at this port in conformity with the above regulations.

2. All immigrants on arrival at quarantine will be subjected to examination as regards their protection from small-pox.

3. The examination of all immigrants by the medical officers of steamships within twenty-four hours after leaving port, and the vaccination of those who give evidence of insufficient protection through previous vaccination, will, if considered by the medical officer at quarantine to have been faithfully and intelligently performed, exempt immigrant passengers from such examination at quarantine as may be necessary to determine whether or not such passengers are protected from the effect of the contagion of small-pox, except where small-pox exists, or has existed, on board the vessel on the passage to this port, in which case the passengers will be examined and vaccinated at quarantine, if not sufficiently protected by previous vaccination.

4. A certificate or card in the hand of each passenger, or the parent or guardian of the passenger, on which shall be written or printed "Vaccinated," and signed by the medical officer of the steamship, will be understood to indicate that such passenger is sufficiently protected by previous vaccination or through the vaccination made on shipboard. All passengers not having such certificate will be considered and treated as exposed or unprotected.

5. The medical officers of passenger steamships will be required to verify under oath the number of persons considered protected by vaccination and small-pox.

6. All persons not protected will be vaccinated or subjected to a quarantine of observation.

The examination of such passengers as are vaccinated soon after leaving the port of departure, and shortly before entering this port to determine results, is earnestly enjoined upon medical officers.

Satisfactory evidence of adequate protection of immigrant passengers from previous vaccination, or through early vaccination by the medical officer of the ship, will not only contribute to the protection of the public health and security, but will promote the interests of passenger lines by saving time and expense at quarantine.

Inspection of emigrants will be made at certain places along the interior line of travel. Uniformity in the form of certificate (or card) given to emigrants is therefore necessary.

The Chair of Gynecology at the College of Physicians and Surgeons, New York.—We understand that Dr. T. Gaillard Thomas has consented to resume his connection with the college, with Dr. Chas. S. Ward as *chef de clinique*.

The Bacilli Tuberculosis.—Ehrlich's method of staining the bacilli of tubercle, as detailed in The Medical News for July 8, has been adopted by Koch, as better than his own process, and is now generally employed in Berlin as a means of diagnosticating tuberculous affections of the lungs.

The Suppression of Juvenile Smoking.—Dr. B. W. Richardson, nothing daunted by the work of resisting the drunkenness of the age, has just been presiding, at London, over the foundation of a society for the suppression of juvenile smoking.

Bartholow's Practice of Medicine, we learn from Canton, is being translated into the Chinese language.

Demonstration of the Bacillus Tuberculosis before the Emperor of Germany.—By request Dr. Robert Koch demonstrated the bacillus tuberculosis to the Emperor of Germany, and explained his views of the pathology of tubercle.

Brighton *vs.* The Lancet.—Suit has been brought against the London *Lancet* by the Corporation of the town of Brighton, for slander on the town and a libel on its authorities for pointing out the defects in its sani-

tary arrangements. *The Lancet* boldly accepts the suit and manfully claims that "if the truth cannot be legally spoken or written as to the sanitary condition of a town, it is time that this should be known, and the public should once for all understand that the supposed guardians of their interests in the matter of health are gagged and silenced by the law."

THE BRITISH MEDICAL ASSOCIATION will hold a Jubilee Meeting at Worcester, August 8, 9, 10, and 11, 1882.

CHOLERA.—A Reuter's telegram states that cholera has broken out in Japan, and in the islands belonging to the Sooloo Archipelago.

THE USE OF AMMONIA IN BAKING POWDERS.—Among the recent discoveries in domestic science and chemistry none are more important than the uses to which common ammonia can be properly put as a leavening agent, and which indicate that this familiar salt is hereafter to perform an active part in the preparation of our daily food.

The carbonate of ammonium is an exceedingly volatile substance. Place a small portion of it upon a knife and hold over a flame, and it will almost immediately be entirely developed into gas and pass off into the air. The gas thus formed is a simple composition of nitrogen and hydrogen. No residue is left from the ammonia. This gives it its superiority as a leavening power over soda and cream of tartar when used alone, and has induced its use as a supplement to these articles. A small quantity of ammonia in the dough is effective in producing bread that will be lighter, sweeter, and more wholesome than that risen by any other leavening agent. When it is acted on by the heat of baking the leavening gas that raises the dough is liberated. In this act it uses itself up, as it were; the ammonia is entirely diffused, leaving no trace or residuum whatever. The light, fluffy, flaky appearance, so desirable in biscuits, etc., and so sought after by professional cooks, is said to be imparted to them by the use of this agent.—*Scientific American*, May 27, 1882.

SEA-WATER IN SCROFULA.—DR. LENA recommends the use of bread made with sea-water in the treatment of scrofula.

DEATH FROM BURNING.—The burning of the Ring Theatre at Vienna gave rise to many important medico-legal investigations respecting the sex and identity of charred corpses, of which Ed. Hofmann and Schultze give a description (*Wiener Med. Blätter*, 1881, No. 50, p. 1538). In determining the sex in cases where the external genitals were completely destroyed, the chief point relied upon was the absence or presence of the uterus and ovaries. In ascertaining the approximate age, external appearances were quite unreliable. The union of the epiphysis with the diaphysis of the humerus, which first takes place at twenty-four years of age; the ossification of the ribs, and more especially the ossification of the larynx, which generally begins between the thirtieth and thirty-fifth year, and is completed in the fortieth year, were found to be the best and most easily ascertained data. In women, the state of the ovaries was important; these being smooth in girls and young women, cicatrized in older women. The hair of the head and beard was generally black, and had to be washed before its natural color could be ascertained. The cornea was generally milky and turbid, as if boiled. Often the obsolescence of the cornea gave to the iris a deceptive blue appearance. The teeth, though calcined and crumbled, were, nevertheless, serviceable in determining the age. The nails, too, in some cases, served for identification. In a large number of cases the blood was of a florid color; and this may have been due to the inhalation of carbonic oxide gas.—*London Med. Record*, May 15, 1882.

DIED, at Norwalk, Conn., on July 8, after a lingering illness, consequent upon Bright's disease, FRANCIS V. BRUSH, M.D.

Dr. Brush was born in Brooklyn, August 26, 1844, and was for many years a resident of that city, his father, the late Major Conklin Brush, having been identified with her interests during a very important period of her history. Dr. B. was a graduate of the College of Physicians and Surgeons, N. Y. He was a leading practitioner and active citizen in Norwalk.

——On June 28, AMÉDÉE LATOUR, the former editor of *L'Union Médicale*.

NOTES AND QUERIES.

IODIDE OF AMMONIUM IN THE TREATMENT OF DIPHTHERIA.

DR. V. SCHRAKIN-ROSS, of Yankton, Dakota Territory, writes to us, recommending in the treatment of diphtheria the use of iodide of ammonium, in solution, internally, with the local application of Lugol's solution to the throat, every three or four hours. By this method he has treated, during the last five months, thirty-two cases, with but a single death. The iodide of ammonium acts, he thinks, by averting the systemic depression which is always present in diphtheria, and by its power of markedly reducing the febrile temperature.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT, U. S. ARMY, FROM JULY 11 TO JULY 17, 1882.

GREENLEAF, C. R., *Major and Surgeon.*—Now awaiting orders, to report in person to the Commanding Officer, Columbus Barracks, Ohio, for duty as Post Surgeon at that post.—*S. O. 160, A. G. O., July 12, 1882.*

BROOKE, JOHN, *Captain and Assistant Surgeon.*—Having reported at these headquarters, is assigned to duty as Post Surgeon at Angel Island, California.—*S. O. 120, Military Division of the Pacific and Department of California, July 7, 1882.*

GIRARD, J. B., *Captain and Assistant Surgeon.*—Relieved from duty at Fort Grant, Arizona Territory, and assigned to duty at Fort Lowell, Arizona Territory.—*S. O. 106, Department of Arizona, July 3, 1882.*

BYRNE, C. B., *Captain and Assistant Surgeon* (Fort Barrancas, Fla.).—Granted leave of absence for one month, with permission to leave the department and to apply for an extension of two months.—*S. O. 68, Department of the South, July 12, 1882.*

HAVARD, VALERY, *Captain and Assistant Surgeon.*—Relieved from temporary duty at these headquarters, and at post of San Antonio, and assigned to duty as Post Surgeon at Fort Duncan, Texas.—*S. O. 68, Department of Texas, July 5, 1882.*

FINLEY, J. A., *Captain and Assistant Surgeon.*—Assigned to duty as Post Surgeon at Fort Concho, Texas (Fort McKavett abandoned).—*S. O. 68, c. s. Department of Texas.*

POWELL, J. A., *First Lieutenant and Assistant Surgeon.*—To report to the Commanding Officer Fort Davis, Texas, for duty (Fort Stockton, Texas, abandoned).—*S. O. 68, c. s. Department of Texas.*

GORGAS, W. C., *First Lieutenant and Assistant Surgeon.*—When relieved by Assistant Surgeon Havard, to report to the Commanding Officer Fort Brown, Texas, for duty.—*S. O. 68, c. s. Department of Texas.*

THE MEDICAL NEWS *will be pleased to receive early intelligence of local events of general medical interest, or which it is desirable to bring to the notice of the profession.*

Local papers containing reports or news items should be marked.

Letters, whether written for publication or private information, must be authenticated by the names and addresses of their writers—of course not necessarily for publication.

All communications relating to the editorial department of the NEWS *should be addressed to No. 1004 Walnut Street, Philadelphia.*

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. XLI. SATURDAY, JULY 29, 1882. No. 5.

ORIGINAL LECTURES.

A CLINICAL LECTURE ON EMPYEMA AND ITS ANTISEPTIC TREATMENT.[1]

Delivered at the Montreal General Hospital, June 24th,

BY WILLIAM OSLER, M.D., M.R.C.P. LOND.,
PROFESSOR OF THE INSTITUTES OF MEDICINE, MCGILL UNIVERSITY.

GENTLEMEN: I wish to speak to you to-day on the subject of empyema and its treatment by the antiseptic method. You saw yesterday a case which was operated upon in this way, and I will first read to you the clinical report.

Mary S., aged twenty-seven, was admitted June 6th. Is unmarried, a servant. Nothing special in the family history. She has been a healthy girl. Four weeks ago she had chills and pain in the left side; no cough or expectoration. She was attended by Dr. McCallum, who diagnosed pleurisy, and on Thursday, June 1st, drew off with the aspirator three pints of turbid, greenish-yellow fluid; the patient was relieved by this tapping, but on the 6th the temperature had risen; she was not so well, and she was recommended to come to the hospital. On admission she was noted to be pale, fairly well nourished, cheeks flushed, temperature 103°. On examination of the chest, the left side did not expand as much as the right. The intercostal spaces were not so distinct, the tactile fremitus was absent. Apex beat to the right of the sternum. On percussion there was dulness over the whole lung, except in the infra-clavicular region. The two sides were of equal size. She complained of a good deal of pain, and the skin was hyperæsthetic. On auscultation, the breathing was exceedingly weak and distant. The evening temperature on the 7th, 8th, and 9th, reached nearly 102°. On the 12th, she was again aspirated and fifty-one ounces of pus removed; she got considerable relief from this. The respirations were reduced from about forty to twenty-four in the minute, and the temperature remained at about 99° in the morning, reaching 100° in the evening. On the 20th, the temperature went up to 103.5°; on the 21st and 22d, it remained at about 102°. She did not seem so well, and we then determined to make a free opening in the chest and treat the case antiseptically. The operation was performed by Dr. Fenwick in the following way. He made an incision in the eighth intercostal space on the left side, on the outer margin of the infra-scapular region, just at the junction of this with the infra-axillary region. He then opened the pleural cavity and put in a silver canula, which was devised several years ago by Dr. Roddick, after repeated trials, for special use in cases of empyema. The canula, which is slightly curved, has the following dimensions: orifice is oval, three-quarters by one-half an inch; a wide flange surrounds it, two and a half by one and a half inches, and provided with eyelets for tapes. The tube is bevelled at its inner end, and measures about two inches in length, and has twelve small perforations. A shorter tube was found to slip out. In cases in which it has been used, this one has given great satisfaction, as it allows of very free drainage from the pleural cavity, and being solid prevents the pressure of granulations and secures a space of constant size through which the pus can exude. As you saw, the most careful antiseptic precautions were taken. About thirty-two ounces of pure pus were removed. It was dressed antiseptically. The cavity was not injected and the layers of antiseptic gauze, soaked in 1 to 40 carbolic acid, were placed directly over the tube, tow was placed outside this, and the side then bandaged. The rule is to repeat the dressing as soon as the discharges get to the edge. Dr. Duncan, last night, dressed the case again, as the discharges had saturated the tow and gauze; and it was dressed again this morning. You have just seen that this patient is in a comfortable condition to-day. The temperature is 98°, respiration twenty-four, pulse one hundred and eight. She expresses herself as feeling very easy, and we hope she will do as satisfactorily as the cases I am about to describe to you. This is the fourth case in which I have had the patients treated on the strict antiseptic plan, and as they have done unusually well, I am at present very strongly impressed with the good results we have obtained.

CASE I.—The first case I had treated in this way was a delicate looking lad, aged 16, who was admitted June 13, 1880, with empyema of left side; all the physical signs well marked. He had been ill four or five weeks, and the chest had been aspirated once by Dr. Ross; the fever was irregular; pulse weak; respirations much accelerated; profuse sweating. The tube was inserted on the day of admission and about four pints of pus removed. This lad was in a very critical condition, very weak and debilitated, and we had grave fears as to the result; however, he did remarkably well. The chest was dressed whenever the discharges reached the edge of the dressing. For some weeks he remained feeble, the temperature going up occasionally as high as 103°. After about a month he began to improve, the discharge got less, and the side of the chest began to fall in. After a treatment of about two months he was materially better, discharge very slight, and on the 27th of September he was discharged perfectly cured and in very good condition, having increased considerably in weight. We had removed the tube some weeks before he left the hospital. I saw him a couple of months afterwards and exhibited him to the Medico-Chirurgical Society; he had then gained forty or fifty pounds in flesh, and had returned to work. There was a slight contraction of the left side of the chest, but he had made a satisfactory recovery.

CASE II. was under our care during last summer session. This was a French lad, aged 20, who was also sent in by Dr. Ross. He had empyema of the left side. It had lasted for several weeks, and he had been tapped once and a quantity of pus drawn off. When he came to the hospital, he had irregular fever and sweating and considerable constitutional disturbance. I thought also at the time that he had some affection of the apex of the right lung, as there were râles in that region. There was universal dulness over the left side, with the exception of the infra-clavicular region, and the usual physical signs of effusion. Dr. Fenwick operated in the way I have described to you; the case was dressed antiseptically, and the lad made a remarkably good recovery. He entered the hospital on the 28th of May, and on July 23d he left completely well, having gained in flesh and with the wound quite healed. I exhibited this lad also, with the other one, before the Medico-Chirurgical Society, and in both of them the result was everything that could be wished.

[1] Reported by Mr. S. A. Abbott, of the Hansard Staff.

CASE III. was also under observation last summer—a man named Clarke, aged about forty-three. He was in the hospital for a couple of weeks with pleural effusion on the right side. There was irregular fever, and we suspected that the fluid was probably purulent. On using the hypodermic needle, we found that there was pus, and he was treated in the way I have already described. The pus was drawn off, and antiseptic dressings were applied every day or every second day, according to the amount of the discharge. This man was admitted April 19 and discharged July 4, perfectly well, having been seventy-five days in hospital. The tube had been removed several weeks before he left the hospital, and at the time of his discharge the breath sounds were audible at the angle of the scapula. He had improved in general health, and he went back to his work. I saw him several months afterwards, and he had kept well.

These three cases of empyema stand out very distinctly in my memory, inasmuch as they are among the few instances in which I have seen good recoveries in this disease. It is always regarded as an exceedingly serious thing for a person to have pus in the pleural cavity. The liability to constitutional disturbance, the difficulty of getting the suppurating pleural membranes to granulate and heal, are well known, and render this disease extremely difficult to treat satisfactorily. Under the antiseptic plan I believe many of these difficulties are obviated. In these cases the temperature after operation, particularly in the man Clarke and in the second case, remained normal, and it would seem that if there is no blocking of the tube, and you get free discharge, this disease, like an ordinary abscess when treated antiseptically, will get perfectly well in the majority of instances, and with very little constitutional disturbance. Of course, when you are in practice, it will be difficult for you to get the complete antiseptic apparatus; perhaps as young practitioners it is not desirable that you should, unless you devote yourselves specially to surgery. This method must, from these circumstances, be confined chiefly to hospital practice, but where you have a case of empyema you can always follow out these general rules: *Get rid of the pus as soon as you can, as completely as you can, and give as thorough drainage as you can to the abscess cavity in the chest*, and if you follow out these you will probably have excellent success in the majority of cases of empyema. A thorough withdrawal of the pus is, I believe, essential, as well as thorough drainage. It does not appear to make much difference whether you wash out the chest or not with carbolic acid or iodine, provided you have an effectual outlet. If the orifice is large, and in a situation where the drainage will be complete, then I do not think washings are so necessary. But if you have a narrow orifice, you may have to make a counter-opening, and put in a drainage-tube, and wash out thoroughly. This is the method usually followed: A drainage-tube is put in and the chest is washed out with dilute carbolic acid, or with dilute iodine. I have seen a good many cases treated that way, and I must say that, excepting in the cases of children, satisfactory recovery has been exceedingly rare. It is notorious that the results in many instances of empyema are most unfavorable; several recent records of such cases have surprised me by their high rate of mortality. One of the best series of cases I know of is that reported by Dr. J. G. Blake, of the Boston City Hospital,[1] who, by means of thorough drainage and a free opening in the dependent portion of the affected side, was able to cure thirteen cases out of nineteen, and two others were very greatly improved. These results were obtained without special antiseptic precautions, and I refer to them with pleasure, for I do not wish you to think that it is only under this plan that cases do well.

As you are aware, in this woman we aspirated the chest first; and the rule is in a case of empyema to draw off the fluid with the aspirator at least once. A few cases do well with a single aspiration, and in children this is almost the rule. But in adults, unfortunately, the case usually goes from bad to worse, unless a very free opening is made. In these four cases the intercostal spaces have been of sufficient size to admit the tube. In some instances the space is not large enough, and you may have to resect a portion of a rib, in order to get plenty of room.

And now a few general remarks on the disease. In some cases the fluid appears to be purulent almost from the outset. In the case of this woman, the fluid, when first drawn off, was turbid, of a cream-yellow color, and probably became purulent shortly after its formation. Of course, the ordinary sero-fibrinous fluid of a pleurisy contains numerous leucocytes, and the conversion of such a simple effusion into a purulent one is a matter of multiplication of these. Purulent fluid is simply the serum densely infiltrated with the leucocytes. In debilitated persons the fluid is much more apt to become purulent than in the strong and healthy. There is but one invariable and sure means of ascertaining whether the fluid is pus or not, and one that is easily applied. Take your hypodermic needle, and thrust it into the chest, and draw off some of it. A simple enough method, but one which is not often enough resorted to. There are numerous practitioners throughout the country who never think of using the hypodermic needle except for purposes of medication, whereas it is of almost as much importance in diagnosis. In cases of pleural effusion, or of doubtful dulness, in the posterior part of the chest, you need never hesitate to thrust the hypodermic needle into the regions affected. It is so simple an operation that it does no harm, while the indications you get from it are of the greatest value.

Professor Bacelli, of Rome, described a few years ago a new sign by which to distinguish between simple and purulent effusions. I tried it in the case of the woman, but it was not very satisfactory. It is as follows: The affected side of the chest is auscultated, and the patient turns the head to the opposite side and whispers. If the fluid is serous, the voice sounds are conveyed to the ear; if it is a purulent fluid, the whispered sounds are not so conveyed. In some instances this method proves useful, and in some it does not. In one case, particularly, it proved to be correct.

Another point worth noting is that, in cases of simple effusion, the patients usually lie on the affected side; whereas, in cases of purulent effusion—why it is I do not know, but it has been specially noted by Dr. Churton, of Leeds, and I have observed it myself—they usually lie on the opposite side.

What becomes of the effusion if it is not removed? It may be absorbed. Adhesions form between the pleura in certain parts, and you may have multilocular empyema, which may be cured naturally, though it will be a struggle and tax the vitality of the patient. It may perforate into the lung to be discharged through the bronchial tubes, which I think is a very favorable way. The cases we have had in this hospital of perforation into the lung and discharge have done exceedingly well. Dr. Ross has had two such cases which recovered perfectly. Dr. Wilkins has a case at present, I believe, in the wards, in which the pus perforated the lung and was discharged by coughing. It may also perforate the diaphragm, but that is rare. It may perforate externally (empyema necessitatis) and discharge for months or leave a permanent pleural fistula. A point to be borne in mind, in cases of left-sided em-

[1] Hospital Reports, 2d Series, 1877.

pyema, when they begin to pass towards the surface, is that they sometimes pulsate, and the pulsation is exceedingly likely to be confounded with that of an aneurism. In the chronic cases the patients have irregular fever, and the prolonged discharge is likely to induce either amyloid disease of the organs, or else the sound lung on the other side becomes affected and they get tuberculous.

The effects of a large pleural effusion, whether purulent or not, upon the lung are very well seen in this specimen, which was taken from a case of empyema, in which the patient died of acute pneumonia of the opposite lung. You see here that the lung is flattened to a cake-like mass, pressed back against the side of the vertebral column.

Among the advantages of the antiseptic method in empyema appear to be:

(1.) Ample provision is made for free and continuous drainage.

(2.) The avoidance of putrefaction; in none of the cases were the discharges in the slightest degree offensive.

(3.) The ease with which the operation is performed and the small amount of trouble entailed in the subsequent dressings.

(4.) The healing is more rapid, and serious consequences, as amyloid disease and phthisis, are less likely to follow.

Note.—July 11. The patient operated upon on the 4th. Has done remarkably well. Temperature normal, except on one evening; dressings changed now every third day; discharge very slight.

ORIGINAL ARTICLES.

PRESIDENT GARFIELD'S CASE AGAIN.

BY FRANK BAKER, M.D.,
ASSISTANT DEMONSTRATOR OF ANATOMY AND LECTURER ON VISCERAL ANATOMY IN THE NATIONAL MEDICAL COLLEGE, WASHINGTON, D. C.

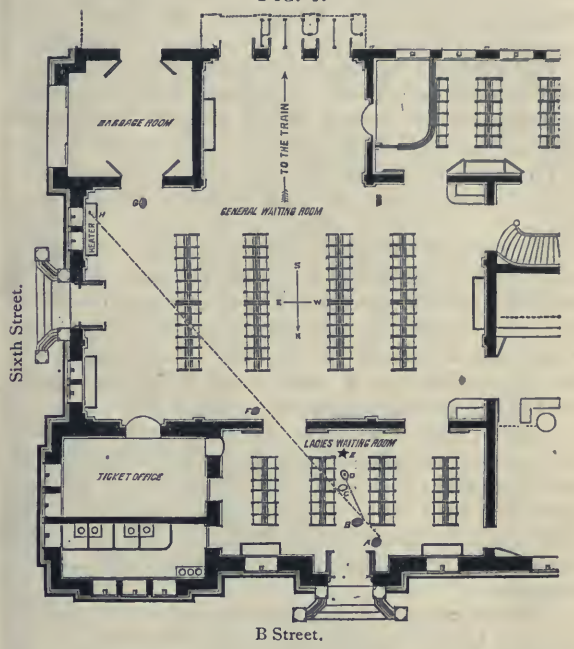
I HAVE read with much interest the article by Dr. White in THE MEDICAL NEWS of June 24th, reviewing President Garfield's case. He rightly states that there is still much misconception regarding several important points, but has, I think, shown that he is himself not entirely free from the error he deplores.

To take up his points in order:

First.—"Did the relative positions of the patient and assassin, at the time of the shooting, afford any indication of the course of the ball as revealed at the autopsy?" Nothing could more strikingly illustrate the difficulty which physicians at a distance have in understanding this fatal case than the statements made by Dr. White in perfectly good faith, and as if the facts were beyond question. He says: "At the time the shooting took place, the President and Guiteau stood about six feet apart, the latter a little to the right of his victim, who was just in the act of turning to the left. . . . All accounts agree that the second shot inflicted merely a slight flesh wound of the arm."

Now, the evidence is conclusive that at no time before he fell did the President turn to the *left*. The only motion of turning was to the *right*. Secretary Blaine, Signor Camacho, Mr. Parke, and Mr. Adams, in their testimony given on the trial of Guiteau,[1] all agree upon this point, and the evidence of Mr. Du Barry is especially conclusive. He was standing at the point marked *F* in the accompanying diagram, which is a ground-plan of the Baltimore and Potomac Railway depot, reduced from the copy used in the trial. Startled by the first shot, he turned towards the sound and saw the President standing, "with his head turned away."[2] If the President had turned to the left, he would have presented his full face to Mr. Du Barry.

FIG. 1.



A. Guiteau's position at first shot. *B.* Guiteau's position at second shot. *C.* President's position at first shot. *D.* President's position at second shot. *E.* Spot where President fell. *F.* Witness Du Barry's position. *G.* Witness Crawford's position. *H.* Spot where first ball was found.

It is also certain that the *second* shot was the fatal one. The positions of the parties, as deduced from a careful analysis of the evidence, are those shown in the diagram. There is no substantial conflict of evidence as to these positions. The position at the second shot is specially well fixed by the fact that the witness Crawford, at the point marked *G* in the plan, could not see the President, though he did see Guiteau in the act of firing.[3]

The fact has been strangely overlooked that the missing bullet has been actually found in a ball of putty contained in the kit of a glazier, a Roumanian named Plokschis. The matter was carefully investigated at the time, and the bullet is in the possession of Colonel Corkhill, the District Attorney. It was not brought out upon the trial for the reason that it was not required by anything presented by the defence. The glazier's kit was standing at the point marked *H* in the plan on the end of a heater under a window of the main passenger hall near the baggage-

[1] Official Report, pp. 121–158. [2] Ibid., p. 182.
[3] Ibid., p. 174.

room, and nearly seventy feet away from the place where Guiteau fired. A glance at the diagram, and an analysis of the evidence as to the corresponding positions of assassin and victim at the first and at the second shots, will convince the most sceptical that the bullet found in the putty must have been the *first* one fired.

If the second bullet was the one found, it could not have cut the President's coat-sleeve, and Guiteau's aim must have been very inaccurate. The testimony is unanimous as to the directness of the second shot. The President himself, as I am informed by Col. A. F. Rockwell, said that he was certain that it was the second shot which took effect.

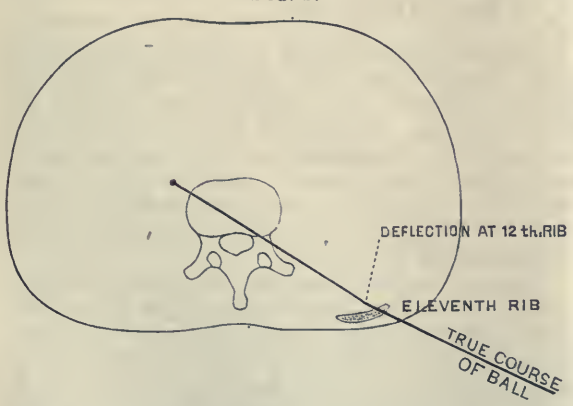
The evidence also shows that while the pistol was held horizontally at the first shot, the muzzle was considerably depressed at the second. This was specially noticed by the witness Crawford, standing at the point *G*. A marked depression would have carried the bullet to the floor before it reached the kit.

The general tradition of the shooting, as it exists among the employés of the railway company, agrees entirely with the positions I have deduced from the evidence. The star in the diagram is the spot where the President finally fell. It is marked on the depot floor by a brass star. His feet were toward the B-Street entrance.

It may, therefore, be considered as established that, at the time of receiving the fatal shot, the President had turned partly to the right, and that the shot was fired from a position diagonally to his right rear, the pistol being held in such a manner as to impel the ball downward, forward, and toward the spine.

It seems strange that any misapprehension of facts so well known should occur, as there was ample opportunity to ascertain the true position of the parties. The witnesses were easily accessible, most

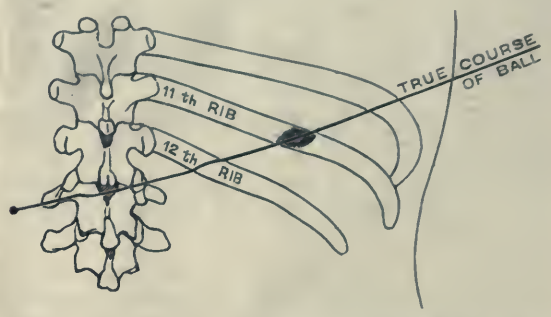
FIG. 2.



of them residents of Washington and employés of the railway company. It is probable that the misapprehension arises from the published report of Dr. Bliss,[1] in which he assumes that a marked deflection must have taken place to carry the ball toward the spine, and an illustration appended[2] apparently shows the point of entrance of the ball as nearer the spine than the point where it struck the eleventh rib. This theory appears to be the one adopted by Dr. White. The contrast between such a course and the one shown by the evidence, becomes striking when placed upon a diagram. Fig. 2 shows this as well as a course not horizontal can be shown in plan.

Fig. 3 is the same, viewed in a vertical plane. The outlines of this latter figure are taken from Fig. 5 of the autopsy report. The location of the points where the ribs were fractured and the vertebra penetrated, may, therefore, be assumed as correct.

FIG. 3.



I am aware that a number of remarkable deflections of the ball have been described as occurring within the body. With the exception of those which took place within the bodies of the vertebræ, these deflections are not confirmed by the official report of the autopsy. In judging of the deflections from the ribs, it should be borne in mind that those who prepare skeletons for anatomical models are in the habit of pushing the ribs upwards and forwards into a position which they occupy in life only during forced inspiration, if at all.

It is perhaps impossible to ascertain the precise angles of deflection from the ribs, as the problem is greatly complicated by their elasticity, and by the impossibility of ascertaining their precise relative position at the fatal moment. It seems probable, however, that the ball was little, if at all, deflected at the eleventh rib, and that what deflection took place was at the twelfth rib after its initial velocity had been somewhat reduced by its first impact.

There is nothing in this case to invalidate the general rule laid down by Hamilton,[1] that conical balls usually go straight to their destination, and Dr. White is not correct when he states that an erroneous conclusion would have been drawn had the physicians relied upon a knowledge of the positions of Guiteau and the President as a means of diagnosis.

Second.—As to probing for the ball. Dr. White correctly states that it would have been unjustifiable to probe the *entire* track of the ball. But that is not exactly the question. Could not the ball have been traced far enough to afford means for a correct diagnosis? It seems beyond doubt that a digital examination, with suitable enlargement of the wound,

[1] Medical Record, Oct. 8, 1881. [2] Ibid., p. 396.

[1] Military Surgery, p. 174.

made immediately after the injury and before the stage of tumefaction had set in, would have sufficiently indicated the course of the ball to show that it had entered the vertebra.

In the course of Dr. White's extensive reading with reference to the case, he has apparently not met with the able article of Dr. Ralph Walsh, of this city,[1] which contains a large amount of original evidence, showing that the *first* examination of the wound was hasty and partial, not even the fracture of the rib being discovered. He quotes from eminent authority to show that the wound should have been enlarged and the spicula from the rib removed to avoid the formation of a pus cavity.

To this Dr. White seems inclined to agree, as he says:

"The rigors which occurred about the 22d of July were due, in the first instance, to the formation of a small abscess under the erector spinæ muscles, possibly caused by the irritation of a small fragment of the broken rib, buried in the contiguous muscle."

It would undoubtedly have been bad surgery to have probed the wound when Dr. Agnew came into the case. But it was far otherwise at first.

the diagram shown below, to which is attached the following certificate:

"We, the undersigned, hereby certify that, on or about the evening of July 7, 1881, this diagram was shown us by Dr. Frank Baker, as representing his idea of the course taken by the ball which wounded President Garfield, July 2, 1881. Dr. Baker further stated that it was his opinion that the ball might have passed through the vertebra and lodged beyond.

"D. WEBSTER PRENTISS, M.D.
"N. S. LINCOLN, M.D.
"SMITH TOWNSHEND. M.D."

The diagnosis was based upon the following points:

(*a.*) *The symmetrical character of the pains in the feet.* Dr. White has been misled. He speaks of the pains in the feet as "at first altogether on the right side, and always much more marked on that side than on the left;" and seems to think they were not of marked severity. Now, these pains were mentioned by the patient immediately after the injury, were very severe, and lasted for a considerable time. Dr. Lincoln, whose eminence and authority are undoubted, and who was with the

Third.—Did the subjective symptoms furnish reliable material for diagnosis? In Walsh's *Retrospect* for October, 1881, is an account of a diagnosis made by me two days after the injury, accompanied by

President most of the time during the day of the shooting, gave me, on July 7, 1881, the information contained in the following paragraph, taken from the article above cited:

"He informed me that his attention had been particularly directed to the pains in the President's feet, which were severe and prolonged, resisting the anodyne effects of hypodermic injections. The patient described the pain as located in the soles of the feet, the region of distribution of the posterior tibial nerve. This at once directed Dr. Lincoln's attention to a possible injury of the spine, and he asked if any difference could be distinguished in the sensations of the two feet. The President, after careful consideration, replied that he could perceive no difference. Dr. Lincoln then

[1] Walsh's Retrospect, October, 1881. See also the same for April, 1882, pp. 307, 308.

[2] This diagram was hastily prepared, without reference to any existing representation of the same region, but it is believed to be correct with regard to the main points involved. It was my intention to carefully revise it so as to make it absolutely correct anatomically, and then to publish it in some medical journal. The large area given to the stomach was shown for the reason that the injury was received directly after a hearty meal, and therefore during a state of distention of that viscus. For the same reason a comparatively small area of liver is shown, it being pushed upward and outward by the distended stomach.

supposed that the spine was certainly injured, or that the ball had possibly passed downward into the pelvic cavity and rested on the hypogastric plexus."

(*b.*) *The hyperæsthesia of the right side of the scrotum at the area of distribution of the ilio-inguinal nerve.* This extended also to the lower abdominal region, the area of distribution of the ilio-hypogastric nerve.

(*c.*) *The vomiting*, so immediate and marked that it indicated an injury to the solar plexus.

(*d.*) *Internal hemorrhage.* The pulse had the peculiar thready character known as hemorrhagic. The vessels lie toward the spine. Hemorrhage from the liver would have been more apparent *externally.*

(*e.*) *The inadequacy of any soft tissue to stop a ball of 44 calibre*, fired with twenty-two grains of powder at six feet range. The vertebræ only could do this.

(*f.*) *Negative evidence.* No paralysis; cord not permanently injured. Daily evacuations and no marked icterus; intestines, kidney, and liver intact.

It is easy to attack these symptoms *separately*, as Dr. White has done, and show that each might be differently interpreted. But he surely has not considered their *cumulative* force. They are like guide-posts pointing to the path of the ball:

"The path of the ball was from right to left, forward and downward. It splinters the eleventh rib, traverses the pleural cavity and the diaphragm, passes *over* the left border of the right kidney, grazes the posterior surface of the liver, enters the psoas, injuring the ilio-inguinal nerve, traverses the body of the vertebra in front of the spinal cord, finally lodging behind the peritoneum near the stomach. For each particular lesion distinct symptoms were shown, which, had not the surgeons been led astray by an error, must have guided them to the course of the ball. The splintering of the rib was recognized, the penetration of the pleura and diaphragm gave rise by diffuse inflammation to the trouble in the lower lobe of the right lung, the grazing of the liver caused the slight jaundice which for a day or two misled the surgeons, the injury to the ilio-inguinal nerve caused the sensations at its distribution, the crushing of the vertebra caused concussion of the cord and the pains in the feet and back, the injury to the solar plexus caused the vomiting, the cutting of the artery, the internal hemorrhage."[1]

Dr. White comments upon the fact that no diagnosis was published until after the autopsy. I think that he will on further reflection understand the feeling which prevented young physicians not having access to the patient from publishing remarks on a case in which the best surgical talent of the country was employed. It is proper for me to state that I was by no means alone in my conclusions as to the course of the ball. Several surgeons independently expressed the opinion that the spine was injured, and it was generally a cause of remark that nothing was heard from the physicians in charge leading to that conclusion. It was supposed that there must be imperative reasons for a contrary opinion evident to those in immediate relation to the patient. Had I not fortunately sketched the diagram showing my views, I would have been as unable to present satisfactory evidence of the fact as many others are. If we add to the subjective symptoms the evidence afforded by the position of the parties, we may well wonder at the "absence of diagnosis," as Dr. White is pleased to call it.

Fourth.—If the diagnosis had been correct, would the treatment have been modified? All know the great skill and care that was lavished on our lamented President. But is it safe to say that no different treatment would have been adopted either in decubitus or surgical procedure had a positive diagnosis been made? I think not. When we reflect how the whole nation hung in suspense over the case, the million hands and heads that were ready to follow the slightest suggestion, I do not think we can predict with certainty the developments that might have ensued.

Fifth.—The cause of death. All acknowledge the rupture of the splenic artery as the immediate cause, the only point in dispute being as to how the rupture was occasioned. Dr. White does not even mention the anatomical difficulty. It is this: the artery arises from the cœliac axis, which is opposite the body of the twelfth dorsal vertebra.[1] It proceeds in a tortuous course in a nearly horizontal direction lying in a groove along the posterior *upper* border of the pancreas, the splenic vein being below and behind it. The ball emerged from the spine at the lower part of the body of the first lumbar vertebra, and was found encysted "below the *lower* border of the pancreas. The pancreas is an inch and a half thick. We are compelled to suppose either that the tortuosities of the artery were such as to cover the entire back of the pancreas, or that the ball after leaving the spine passed upward for an inch and a half in a nearly vertical direction, and then down again. The splenic vein which apparently would present more nearly in the track of the ball, was not injured.

Dr. White suggests a "slowly developing inflammation and ulceration extending from the track of the ball." But the report of the autopsy has told us nothing of this. Arteries are almost the last structures to give way to ulceration.[2] Neither is it likely that the vessel was wounded by a spiculum of bone, for the spine is so thoroughly protected in front by ligamentous and tendinous attachments that the detachment of spicula is "difficult if not impossible."[3]

Admitting that it was anatomically possible for the ball to impinge on the artery, it must then have been nearly spent. Would it not have *pushed aside* an artery with strong and elastic coats like the splenic?

Again, how could a traumatic aneurism exist for eighty days in loose subperitoneal tissue, which can readily be peeled up anywhere in the lumbar region by moderate force? The splenic artery is equal to the brachial in size.[4]

Sixth. Was the wound necessarily mortal? Dr. White by no means does justice to the case of the

[1] Walsh's Retrospect, loc. cit.

[1] Power's Anatomy of the Arteries, p. 249.
[2] Agnew's Surgery, vol. i. p. 531.
[3] Hamilton's Military Surgery, p. 337.
[4] *Henle.* Gefässlehre des Menschen, s. 167.

other side. Probably no two wounds were ever *exactly* alike. The amount of affirmative evidence is necessarily small. Gunshot wounds of the bodies of vertebræ not immediately fatal are rare and difficult to diagnose. Opportunities for post-mortem examination of cases of recovery are much rarer. Dr. Walsh[1] cites the following case reported by Dr. Johnson Eliot, one of the most distinguished surgeons of this city, and formerly Demonstrator of Anatomy in the college to which I have the honor of being attached. He says:

"While I was Demonstrator of Anatomy, National Medical College, a cadaver was brought into the dissecting-room for dissection. After it was dissected, the janitor, while cleaning the bones for the purpose of making a skeleton, observed a hard substance in the body of the second or third lumbar vertebra. He drew my attention to it, and, upon examination, I discovered that it was a bullet deeply imbedded in the cancellated tissue of the body. The injury was such a remarkable one, in view of the man's apparent excellent health, that I called it to the attention of Dr. Thomas Miller, then Professor of Anatomy in the College. He expressed great surprise at the injury and interest in the case, and desired me, if possible, to obtain a history of it. After considerable inquiry, I learned that the man had been a marine in the United States service many years; had served his period of enlistment, and been discharged, subsequently engaging in another vocation, and dying in this city of pneumonia. The history of the case and appearance of the body presented no evidence of recent gunshot injury."

Again, in *The Lancet* of May 27, 1881, I find the following abstract of a case from *Gaillard's Medical Journal* (which I have not at hand), and vouched for by Dr. Gaillard. The comments are those of *The Lancet*.

"The patient was an officer in the American army, who was wounded at the battle of Seven Pines, May 31, 1862. He was first struck by a minie-ball, which entered just outside the right anterior inferior iliac spine, and passed out through the buttock without injuring the bones. A little later a ball passed through the calf of his right leg, and he then fell face foremost into the mud. While lying in this position, another minie-ball struck him on the right of the spine, below the false ribs. No symptom of paralysis or visceral lesion supervened. Little or no effort was made to find the bullet, and he left the hospital in a month. The following winter he again served in the army, and bore great fatigue. At the close of the war he returned home in good general condition, but suffering pain in his spine, which did not, however, prevent his undertaking severe physical labor. So he went on until 1875, when, after some very heavy lifting, he was seized with severe pain, and became emaciated and disabled. The sinus in his back had been discharging all this time. This was now explored. A free incision being made down to the body of the first lumbar vertebra, which was felt at the bottom of the wound, the finger could be passed round the part of the body of the vertebra, and the bullet was felt fixed in the bone on the left side. With considerable difficulty the bullet was removed. It was found to have cut a deep groove or tunnel round the right side of the first lumbar vertebra, and to have splintered the last rib. The man's general condition improved considerably at once, but six months later he was again attacked with fever and great pain and swelling on the left side of the spine. Three or four weeks later the swelling was opened, and large quantities of pus "blackened with powder" were discharged. Following this came several small pieces of bone and a piece of cloth two inches long by a quarter of an inch wide, part of the binding of his pantaloons; and a few days after this a piece of bone, with a cup-shaped depression that exactly fitted the extracted bullet, came away. From this time the man steadily improved; the two sinuses closed up, "and he now has no pain in his back, feels well, and is in stout and robust health." This case, interesting in itself, is still more so when considered in relation with the wound of President Garfield. The original injury in the two cases was nearly similar, but it is noteworthy that the patients were very different—one was a young man, the other considerably older; and the course taken by the pus was also different in the two cases. But this case shows conclusively that a gunshot wound of the body of a vertebra is not necessarily a fatal injury, as was hastily and unwarrantably stated in reference to President Garfield's case."

[1] *Loc. cit.*

It may be further said that Dr. White's analysis of Dr. Hammond's citations, still leaves untouched the fact that eminent authorities recognize the possibility of recovery after a gunshot wound of the bodies of vertebræ.

I purposely abstain from advancing any theory or drawing any conclusions. Deploring, no less than Dr. White, the misconceptions which still exist, I have given the reader well-authenticated facts from which he can make his own deductions. If, with such facts as we have shown could have been obtained at the first moment of inquiry, science cannot reach a diagnosis, the energy of the profession should be directed to finding means to do so. If the data for a diagnosis did exist, it can be no excuse for the neglect to make use of them, to allege that the termination of the case would not have been affected.

DISPLACEMENT OF THE SPLEEN AND PANCREAS; SLOUGHING OF BOTH ORGANS; GANGRENE OF INTESTINES.

BY W. L. ESTES, M.D.,
MEDICAL SUPERINTENDENT OF ST LUKE'S HOSPITAL, SOUTH BETHLEHEM, PENNSYSVANIA.

CONGENITAL deviations from the normal positions have been reported of all the solid abdominal viscera. Wandering kidneys are frequently met with; displaced livers now and then; and dislocated spleens are not uncommon. But in all the medical literature that the writer has been able to consult, he has not found a case of spleen and pancreas dislocated into the right iliac fossa. Thinking that a report of such a case might be interesting to the readers of THE NEWS, the history and autopsy of the subjoined case are given.

While the reporter was House-Surgeon in Mt. Sinai Hospital, New York, in 1880, Rosa P., nineteen years of age, Hungarian by birth, was admitted into the gynecological ward as a case of "Abdominal Tumor." She was admitted November 2, and gave the following history: Family all perfectly healthy; she herself had been perfectly well up to three years before coming under observation, when she had a very severe attack of what she said her physician called "*liver fever*," which confined her to bed one whole winter. During her sickness she

noticed a "swelling in the right side," but it seemed to disappear entirely after her convalescence. Eighteen months after this she immigrated to America, and almost immediately was again sick with similar symptoms as at her former attack, but of less degree and much shorter duration. Since then she has had three attacks, all marked by pain in the right iliac region, swelling of the abdomen, and slight rise of temperature. After three days she is always able to get out of bed and return to her work (that of an ordinary domestic) without any inconvenience, save slight soreness and pain in the abdomen, which disappears in a few days. Her present attack began seven days before admission. She arose feeling as well as usual, and went to work. In a short time she was seized by such violent pain in her abdomen that she was obliged to return to her bed, and has remained there until brought to the hospital. She says she had not lifted any heavy weight, nor made any extra muscular effort, the day preceding or the morning of her attack; that she knows of nothing that could have brought it on. Her bowels had been regular; menstruation also regular and painless. On admission, the patient presented the appearance of a very muscular and well-developed girl. Ruddy cheeks, and full, rounded form, indicated her previous good health. She seemed to suffer intense pain, referred to the whole abdomen. She could scarcely walk, and when she attempted to do so, bent far forward, in order to relax the abdominal muscles as much as possible. Physical examination showed abdomen slightly distended generally; small umbilical hernia readily reducible; no particular tenderness over any part of the abdomen; palpation discovered a hard, or rather *solid* feeling, mass, occupying the whole of the right iliac region, extending over into the left iliac region to within seven centimetres of the left anterior superior iliac spine, and from this point diagonally upwards (with a distinct free border, having no discoverable notch or indentation) across the umbilical region, into the right hypochondrium, to within five centimetres of the lower border of the ribs; this whole area having a perfectly solid feel, except along the free border, where a peculiar crepitation was felt upon grasping it between the fingers. Percussion note perfectly dull over the whole tumor; no tenderness; hypodermic needle introduced without withdrawing fluid. Vaginal examination showed that the mass filled the right iliac fossa completely, extending behind the uterus, and pushing it so far forward that it was almost shoved over the symphysis pubis—and reached into the left iliac fossa; perfectly solid and *immovable.* Changing of the position of patient in various directions seemed not to vary the position of the tumor the least. Rectal examination added no new light. The form, feel, percussion, and aspiration suggested that it might be the liver displaced downward, its right lobe resting in the iliac fossa, and left lobe upward to the right. *Palpation and percussion over the normal site of the liver showed that organ in place, however;* stomach much distended; percussion over the natural splenic area *seemed to show the spleen in place.* There was certainly sufficient dulness to indicate the presence of a small viscus. Examination of urine negative. Other organs all seemed healthy. Temperature upon admission, 100° Fahr. Complete rest in bed with opium and belladonna suppositories to relieve the pain, and one mercurial purge were ordered.

On the third day after admission, the patient's condition remaining about the same, Dr. Noeggerath, the visiting gynecologist, was called in to see her. The patient was thoroughly examined by us both, under an anæsthetic, without any further discovery except that the right ovary could not be felt, while the left one was easily found. Dr. Noeggerath concluded it was a case of sarcoma of the right ovary.

On the tenth day, six days after this examination, the patient complained for the first time of exquisite tenderness in the right iliac region, and soon developed a case of marked general peritonitis, which subsided after ten days of opium internally and hot water applications externally. It was at this time noticed, much to every one's surprise, that the tumor was markedly lessened.

Four days after this, it is noted, "tumor almost entirely disappeared, only slight induration felt in right iliac region. Vaginal examination shows a corresponding disappearance of the mass from the pelvis. Patient extremely weak and reduced." At this time extreme gastric irritability manifested itself. The patient was at first unable to retain the milk punch which was given her in small quantities, then rejected milk and lime-water as soon as taken, and steadily grew worse, until she vomited almost incessantly, notwithstanding the administration of every remedy known for vomiting, one after the other. Three days of this sufficed to end her life; she died on the 27th, twenty-five days after admission. After the peritonitis, she had no considerable rise of temperature, nor did she complain of any pain or tenderness in the abdomen of any marked degree, until just before she died, when her temperature shot up to 103° Fahr., and she had great pain in the abdomen.

Autopsy, twenty-four hours after death. — Body reduced to skin and bones, so great was the emaciation. Percussion over right iliac region was still, as it had been several days before death, *dull*, almost *flat.* No solid mass felt anywhere over the previously *solid* area. Upon opening the abdominal cavity, a very marked fecal odor was at once noticed. As the incision extended below the umbilicus, there was a large discharge of very fetid pus. Upon examination, it was found that the pus proceeded from an abscess cavity, extending from the level of the umbilicus to the bottom of the cul-de-sac of Douglas, involving the whole right side from this level, and extending to the left no further than the middle line. Intestines in juxtaposition with the abscess, gangrenous, and the ileum was found perforated about its middle, near the mesenteric attachment. A small quantity of blood extravasated into the peritoneal cavity, and quite a large quantity into the intestine itself. Liver much enlarged, and paler than normal. Kidneys also enlarged and pale. The spleen could not at first be found; at last, however, a grayish, sloughy mass, which seemed at first to be

mesentery, upon close examination proved to be the *pancreas*, extending, tail foremost, almost vertically downwards, the head retaining an almost normal position, while the tail was found in the right iliac fossa, near the middle line. In this fossa, after searching some time, a small, flat, soft piece of detached tissue, about five centimetres long by three centimetres broad, was found, which proved, upon minute examination, to be remains of the spleen. That it was splenic tissue, several gentlemen who were present at the autopsy, and others who examined it afterward, bore witness.

The stomach's ligaments seemed elongated, and the organ itself seemed dragged slightly downward. The other organs were normal.

The etiology of this case must be simply conjectural. My own theory—the only one I know of with reference to it—is as follows: It would seem that the patient had congenitally a "wandering spleen." Belonging to the poorer class of Austrian peasantry, she was accustomed to undertake the work of a common farm laborer. While at work in the fields she made some violent effort, and thus by muscular action forced this spleen, with elongated attachments, bodily into the right iliac region. This was followed naturally by very violent inflammatory action, giving rise to her first attack, which her physician called "*liver* fever"—the passive congestion and consequent enlargement of the spleen being very naturally in that situation taken for the liver. The sudden displacement, so powerfully brought about, gave the bloodvessels and nerves, common to the pancreas and spleen, no time to accommodate themselves to the changed condition, and their connection, together with the fold of peritoneum from the pancreas to the spleen, sufficed to bring the tail of the pancreas, by a sort of somersault, along with the spleen. The extreme tolerance of the abdominal viscera to abnormal relations and pressure, is constantly exhibited in cases of wandering kidneys and spleens, as well as the pathological conditions of abdominal tumors involving the various organs. It would not appear impossible, therefore, that the displaced viscera in this case should have returned to the proper performance of their functions, and that the patient should have regained a tolerable degree of health. In this position there must have been a continual passive congestion of the spleen, which would, and no doubt *did*, lead to an interstitial splenitis (cirrhosis or fibroid degeneration). The recurring attacks may be explained by causes similar to first, *i. e.*, some slight over-exertion with the organ in its then position would easily excite a local inflammation of the peritoneum or cellular tissue around the caput coli. Her last attack was probably due to malaria. An already chronically enlarged spleen, its parenchymatous tissue well-nigh replaced by fibroid tissue, suddenly congested by a specific morbific agent—the bloodvessels being necessarily implicated in the previous tissue changes—with chronically dilated walls of vessels and loss of contractility, there would be almost a complete stasis, enormous extravasation, and all the concomitant changes of a destructive inflammation, the result being extensive suppuration, and as the sequel proved, general peritonitis, and finally sloughing of the spleen and pancreas.

The above is, of course, merely offered as one supposition, and the most plausible one that has yet suggested itself. The actual facts at all events, as far as known clinically, are faithfully given. I should be glad to have any other explanation of the phenomena that may occur to any member of the profession.

FRACTURE OF SKULL; TREPHINING; DEATH FROM ABSCESS.

BY R. A. KINLOCH, M.D.,
OF CHARLESTON, S. C.

(*Read at the Meeting of the South Carolina Medical Association, April, 1882.*)

SCOTT MAXWELL, colored, æt. thirty-five, admitted into City Hospital, February 11, P.M., 1882. While working in a pit at one of the Phosphate Works outside of the city, was struck upon the head by another workman with the flat portion of a shovel. He was felled to the earth, and was senseless for some time. After a few hours, recovered sufficiently to be sent in a wagon to the hospital. He then presented the mixed symptoms of concussion and compression, the former predominating. He was placed in bed, head elevated and kept cool, and absolute quiet enjoined. Later an enema was given to empty the bowels, and large doses of potas. bromide directed to be given in the event of restlessness. Upon careful examination no fracture could be discovered, but only a slight abrasion of scalp over right parietal bone, with bloody extravasation under scalp, and general swelling of the soft tissues over the vertex.

Feb. 16.—This A.M. it was reported that patient had had several convulsions in the night, and during one of these had fallen out of bed before the nurse could reach him. The symptoms of compression were more marked, but were not extreme, the pulse was slow, and the temperature slightly below normal.

Dr. Kinloch expressed the opinion that there was likely a fracture of the inner table of the skull, with bloody extravasation upon the dura mater, and beginning effusion, possibly a fissure of skull running into the base. He concluded that the case would likely be hopeless, but that trephining offered the best chance for life.

At 12 M., patient was carried before the medical class, and operation performed under chloroform and with antiseptic precautions. The natural inference from the abrasion over the right parietal bone, and the evidences of contusion there, was that this side of the head had received the force of the blow. The trephine was consequently applied at this point. Upon opening the skull the dura mater was found exceedingly tense, and seemed to crowd into the opening made by the trephine. No signs of fracture or of bloody extravasation beneath the skull could be discovered. The tension of the dura mater was such that it was thought proper to puncture the membrane. This liberated a considerable amount of bloody serum. No further procedure was considered advisable. Wound was dressed with car-

bolized oil upon lint, and several layers of borated cotton superimposed. Patient was put to bed, ice cap ordered to the head, thirty grains of potas. bromide to be given three times a day, and one grain of calomel every four hours. I omit the clinical notes for the first two days.

19th.—Up to this date the patient's temperature had remained below normal. To-day at 9 A. M. the temperature was 102.2°; pulse 72. 9 P. M., temperature 103°; pulse 76.

20th.—9 A. M., temperature 103.5°; pulse 92. 9 P. M., temperature 103°; pulse 76. Calomel stopped to-day, as salivation was evident.

21st.—9 A. M., temperature 100°; pulse 92. 9 P. M., temperature 101.2°; pulse 96.

22d.—9 A. M., temperature 101°; pulse 80. 9 P. M., temperature 101°; pulse 92.

23d.—9 A. M., temperature 102°; pulse 92. 9 P. M., temperature 103°; pulse 100.

24th.—9 A. M., temperature 104°; pulse 64. 9 P. M., temperature 106.5°; pulse 60.

25th.—During day, temperature 103.5°; pulse 68.

26th.—During day, temperature 103°; pulse 84, and scarcely to be felt. Patient expired this evening.

27th. Autopsy.—Skull was found fissured through the whole parietal bone of the *left side*, the fissure running to the base; bloody extravasation between skull and dura mater on *left side*. Between dura mater and brain on *right side*, and extending to frontal region, was a large collection of pus. There was also a small abscess in the substance of the right cerebral lobe, contiguous to the opening in the skull made by the trephine. This abscess was evidently the cause of death.

Remarks.—It will be observed that my inferential diagnosis as to fracture and bloody extravasation was correct, but the fracture was on the opposite side of the head, and not confined to the inner table. It is probable that the patient had received more than one blow with the flat of the shovel, and hence we were deceived in attempting to locate the injury of the skull. The character of the blow was such as to warrant the belief that the inner table had chiefly suffered. Such a blow might well illustrate the views of Mr. Teevan in regard to fracture commencing in the *line of extension*, and not in that of *compression*. Fractures of the inner table alone must be ever obscure, and their diagnosis *always inferential*. The use of the trephine in skull injuries generally, is still a matter of disputation. The propriety of operating after a mere inferential diagnosis will be objected to by the majority of prudent surgeons, who, nevertheless, recognize the close analogy between punctured fractures and simple fractures of the inner table alone. Listerism will perhaps make many surgeons more disposed to venture an operation in head injuries, as they are in injuries of other regions. The conservative opinions of Stromeyer, who thinks it fortunate that fractures of the inner table escape detection *because they thus also escape operation*, will hardly check the tendency of the age to bold experimental procedures. We are indebted to Dr. Lidell, of New York, for most valuable reports and able arguments in controversion of the views of Stromeyer, and those who think with him. I am rather inclined to favor a hopeful and a progressive surgery, and, as my practice in the above case will show, to give the sufferer the chances of an operation in doubtful cases. The result of my venture in this particular instance, however, may be regarded as an argument against the doctrine I have accepted. The most reasonable conclusion is that my patient died from the operation. Whether he would have survived under expectant surgery is a matter only for speculation.

HOSPITAL NOTES.

HOSPITAL OF THE UNIVERSITY OF PENNSYLVANIA.

(Service of PROF. ASHHURST.)

URACHAL FISTULA.

(Reported by H. R. WHARTON, M.D., DEMONSTRATOR OF CLINICAL SURGERY IN THE UNIVERSITY OF PENNSYLVANIA.)

W. K., aged nine months, was sent to PROF. ASHHURST'S clinic by Dr. A. J. Marcy, of Riverton, N. J., and upon examination presented a flattened tumor about the size of a filbert, occupying the position of the umbilicus, it was covered with mucous membrane, and in its centre there was a depressed opening through which occurred a constant discharge of urine; there was no phimosis or other obstruction to the free passage of urine through the urethra.

The case was diagnosed as one of urachal fistula or patulous urachus, and an operation was decided upon for its relief.

The child was etherized, and a slender cautery iron heated to a dull-red color having been dipped into the fistulous tract, so as to destroy its mucous lining, a needle armed with a double ligature was passed through the base of the tumor, the needle was withdrawn, and the ligatures tied so as to completely strangulate the mass; which was then cut off below the ligatures, and the cautery thoroughly applied to the stump. The case was kept under observation for several days, when, as the patient presented no unfavorable symptoms, he was sent to his own home.

Several weeks after the operation Dr. Marcy reported that the slough had separated, that no urine had escaped from the fistula, and that the wound had healed, leaving an umbilicus normal in its appearance.

Remarks by DR. WHARTON: Urachal fistula is caused by a patulous condition of the urachus, which, it will be remembered, represents a tube in the embryo extending from the bladder to a pouch called the allantois, situated outside of the abdominal walls; this tube is obliterated in early fœtal life, and is recognized after birth as a band extending from the umbilicus to the bladder.

The patulous condition of the urachus is generally attributed to some obstruction to the free passage of urine from the bladder, as a narrowing of the meatus, complete atresia, imperforate prepuce or phimosis.

In addition to the annoyance caused by the constant escape of urine accompanying this condition, the formation of calculi has also taken place in the patulous urachus, as is shown by the case of Boyer, reported by Gross, and cases reported by Cabriol, Paget, Amussat, Vosburg, and Henriette. The number of reported cases of urachal fistula are few, and in many of the text-books on surgery the condition is not described.

Agnew[1] mentions a case of incomplete urachal fistula

[1] Agnew, System of Surgery, vol. i. p. 388.

in which the umbilicus became distended when urine was allowed to accumulate in the bladder.

Ashhurst[1] has seen two cases, and records five others seen by Guéniot, Jacoby, Rose, Charles, and Worster.

Gross[2], under the title of patent urachus, describes the condition and mentions several cases.

Bryant[3] mentions one case seen by himself, which was not subjected to operation.

The treatment of this condition consists first in the removal of any obstacle to the free escape of urine from the bladder, and if this should not accomplish the object, the fistula may be closed by a plastic operation, by the use of the ligature, by the application of the actual cautery, or, as in the case reported above, by the use of the ligature and cautery combined.

MEDICAL PROGRESS.

EXTIRPATION OF THE UTERUS BY THE VAGINAL METHOD.—DR. EUGENE HAHN gives in the *Berliner klin. Wochenschrift* his experience of this operation. He has performed it seven times, with two deaths. Five out of the seven were for carcinoma, and two for prolapse. One of the deaths was from peritonitis, and the other from bronchitis, with pelvic peritonitis and pelvic abscess, all of which conditions are stated to have been present before the operation. The following is the method of performing it practised by Dr. Hahn: During the twenty-four hours prior to the operation the vagina is repeatedly syringed with a five per cent. solution of carbolic acid. Shortly before the operation, if disinfection should not appear complete, the surface of the new growth is scraped, and a twelve per cent. solution of chloride of zinc is applied. The tumor is seized with broad toothed forceps, and, by incisions round it, is separated from the healthy tissues. Anteriorly the bladder is dissected off, and the peritoneum opened; and then posteriorly the peritoneum is opened in like manner. Then the structures contained in the right broad ligament are successively ligatured from before backwards. The ligatures are passed with an aneurism needle. The tissues between each ligature and the uterus are secured by catch forceps, then the ligature tied, and the tissues divided between the forceps and the uterus. This being done, two fingers are introduced into the peritoneal cavity, and the uterus seized, and then the left broad ligament tied and cut through in the same manner as the right. The uterus having been removed, and the ligatures cut short, the abdominal cavity is washed out with a one-third per cent. solution of salicylic acid, and all blood-clot is removed. The most minute care is taken to stop all hemorrhage. Then the speculum is pushed up until the intestine is visible, and iodoform is sprinkled over it, and then, the speculum being gradually withdrawn, the parts exposed are likewise dusted with iodoform. Lastly, iodoform gauze is put in the vagina. In from twenty-four to forty-eight hours the dressings are usually soaked with discharge. The gauze is then removed, the vagina gently syringed with lukewarm solution of salicylic acid, the parts again dusted with iodoform, and iodoform gauze put in the vagina. This is repeated every twenty-four or forty-eight hours for eight or ten days, after which the discharge commonly ceases.—*Med. Times and Gazette*, June 24, 1882.

NEUROSES ASSOCIATED WITH THE VAGUS NERVE.—After noting the frequency of cardiac irregularity from indigestion, DR. ROSENBACH records (*Deutsche Med. Woch.*, 1882, No. 12) a case of cardiac irregularity caused by the horizontal posture, and a case of temporary central paralysis of the vagus nerve. The patient in the first case was a prematurely old man, aged 55, who complained that, as soon as he lay down in bed, he had a feeling of præcordial anxiety, and usually awoke in great distress, with the hands cold and stiff. With the exception of slight anæmia, some signs of arterial sclerosis, and a slight emphysema, there was nothing abnormal in his condition. The digestive functions were normal. His pulse in the erect posture was 72, regular, and moderately full; but, on his assuming the recumbent posture, with the head low, it fell to 60 or 64, and became irregular and intermittent, all which characters disappeared almost immediately on his assuming the erect posture again. Dr. Rosenbach, considering that he had excluded all other possible causes, attributes this phenomenon to the change in the outflow of blood from the cranial cavity. This outflow being much less free in the horizontal than in the erect posture, as shown by the more rapid current in the veins at the root of the neck when the erect posture is assumed, he considers that in a patient with arterial sclerosis the tonus of the vagus and of the vasomotor nerves produced by the venous blood will cause retardation of the heart's beat, with increased arterial tension. The patient in the second case was a man, aged 31, affected with phthisis. While in hospital, he was attacked with vertigo and headache, his pupils being extremely narrow. Two days later he became insensible, breathing once, or, at most, twice a minute, while at the same time the heart was extremely frequent and tolerably full. Under artificial respiration, carried on for an hour and a half, the patient recovered. Each time the artificial respiration was stopped, the patient again ceased to breathe, and became cyanotic. That the vagus could still conduct impulses, was shown by the fact that electric stimulation with a strong current reduced the heart's beats from 156 to 100 or less, per minute. After the above period, Cheyne-Stokes's respiration set in, and for two hours longer the patient required to be roused occasionally. A month later, the patient died of tubercular meningitis. Dr. Rosenbach puts down the symptoms in this case to a central paralysis of the vagus, owing to a disturbance of nutrition in the respiratory centre of the medulla oblongata.—*London Med. Record*, June 15, 1882.

TEMPERATURE IN CARDIAC DISEASE.—A monograph upon the above subject has recently been published by M. SABATIER. His researches embrace the determination of the local temperature of the præcordia, as contrasted with the axillary temperature. He states the normal temperature of the præcordial region as 36.1°C. (about 97° F.), liable, however, to variations in different subjects. In pericarditis the axillary temperature is much raised in acute cases, but not influenced in chronic and subacute cases. The præcordial temperature is increased in acute and subacute pericarditis, but where there is much fever, as in acute rheumatism, the præcordial temperature is lower than the axillary. When the local inflammatory process is very intense this difference may be reversed. When right-sided pleurisy coincides with pericarditis, local thermometry indicates the relative intensity of the two inflammatory processes. During endo-pericarditis the local temperature does not subside so soon as the general. In endocarditis there is no local rise in temperature, a point of distinction from pericarditis. In cardiac hypertrophy the præcordial temperature is the same as, and sometimes lower than, that of the opposite side. Vesication applied to the præcordia keeps the temperature at a high level for several days. Numerous tracings are given and, although the subject is limited and, per-

haps, hardly sufficiently fruitful, considering the labor expended upon it, it is the first contribution to local cardiac thermometry that has been made. The author believes that the method is a valuable aid to diagnosis, and that the local temperature of the cardiac region should always be estimated. It is of most importance at the close of the acute period, when the axillary temperature has become normal.—*Lancet*, July 1, 1882.

THE TREATMENT OF ERYSIPELAS.—DR. HASTREITER recommends the treatment of epilepsy by painting with oil of turpentine, on the following grounds:

1. It can be employed on the most sensitive patients, does not require any skill, and can be applied by the patient himself as often as may be necessary, and the irritation produced by excessive friction is avoided. During its application the eyes should be protected by a pad.
2. When employed frequently enough this method is perfectly safe, and tends to produce a rapid cure.
3. Oil of turpentine can be procured everywhere.
4. All other dressings are unnecessary.
5. Internal antipyretic treatment is only rarely necessary; usually all that is necessary is to bathe the body with cold water, and to make use of cold applications to the head.
6. The inhalation of the vapor of turpentine can perhaps act as a preventive of the extension of the disease to the air passages.
7. When employed at the outset of the disease it may abort the morbid process.
8. The oil of turpentine may also be employed in phlegmonous inflammation other than erysipelas.—*Wiener Med. Presse*, June 18, 1882.

CHARACTERS OF THE URINE IN YELLOW FEVER.—DR. CULBERTO PENA (*La Escuela de Medicina*, Mexico, Feb. 15, 1882) publishes a series of observations which he has made on the condition of the urine in yellow fever. In nine cases in which the vomiting was present, albumen was only found in one, and then in very small quantity. In the course of an epidemic that he had the opportunity of observing, albumen was absent in one-quarter of the mild cases and in thirty-seven per cent. of the grave cases. The reaction was nearly always acid, being alkaline or neutral in only four per cent. The color was variable, being at first clear, but becoming turbid during the course of the disease. Bile pigments are not present as a rule, being only met with twice in two hundred examinations.—*Journ. de Méd. de Paris*, June 24, 1882.

PORRO OPERATIONS.—The last case reported was that of Dr. Dozzi, of Italy: operation performed on March 10, 1882. The subject was a dwarf, 28 years old, measuring in height (79 cm.) only 31⅛ inches, and having a deformed pelvis. The membranes had been ruptured eight or nine hours when the section was made; the fœtus was delivered alive but died before the operation was concluded; the woman died of shock in 24 hours.—*Gaz. Med. Ital. Prov. Venet.*, No. 22, June 3, 1882.

This case gives Italy 36 operations, with 22 deaths and 14 recoveries. There have been in all 91 operations, as far as reported, with 38 recoveries.

Ignatio Cataliotti's Case.—This was first reported from Italy as the work of Dr. Camminiti, of Messina. Dr. Cataliotti operated at Palermo, on October 28, 1880, on a woman 40 years of age, affected with a large fibro-myoma of the uterus, and ascites; the fœtus was delivered alive, and the woman recovered.—*Stamperia Militare*, 1882.

Dr. Negri also reports a case under the head of "*Bayer*," of Stuttgart. Our tabular record shows this operation to belong to Prof. Fehling, May 4, 1881; the woman and child were saved. Operation performed after the modification of Müller.

Dr. Marchand, of Paris, has performed Prevôt's operation, *i. e.*, the amputation of the uterus through the cervix and its removal, in a case of rupture of the organ in labor. The child was dead, and the woman died of peritonitis. This method has not yet saved a case of rupture. The uterine suture promises much better results. Let the abdomen be thoroughly cleansed of blood, and the uterus well sutured with silver wire or pure silk, at short intervals, along the whole line of the laceration.

A CASE OF PHLEBECTASIS.—RIEDEL (*Centralb. f. Chir.*) reports the case of a man 42 years old, always healthy, member of a family in which apoplexy frequently occurred, who acquired in the course of two or three months a stupid expression of countenance, with, later on, determination of blood to the head, rushing sounds in right ear, giddiness on stooping, and troublesome burning of face. A few days later there was well-marked facial cyanosis, especially on the right side. The veins of the chest on the same side were full and distended, and at the anterior border of the axilla a tortuous varicose vein was visible. In the right supra-clavicular fossa there was a tumor the size of a hen's egg, from whose upper margin the dilated external jugular vein ran upwards. Pressure on this non-pulsating tumor caused it to disappear, whilst the patient experienced loud rushing noises in the ear. On cessation of pressure, the tumor, whose lumen could be traced for some distance into the chest, resumed its former size. There was a similar, though much smaller, tumor on the left side. The heart and other organs were found to be normal. Under daily injections of ergot the swellings rapidly disappeared, becoming flatter and harder, and the subjective symptoms ceased. As a central obstruction of the circulation may be excluded, Lindner is inclined to regard a chronic phlebitis, specially localized in the neighborhood of the valves, as the cause of the symptoms described. Owing to this process the venous walls become affected in such a manner that they give way under the moderate pressure of the blood-stream, retarded somewhat by the altered valves.—*Edinburgh Med. Journ.*, April, 1882.

THE CAUSES OF THE NORMAL JUGULAR PULSE.—M. FRANÇOIS-FRANCK has communicated to the Société de Biologie (*Journ. de Méd. de Paris*, No. 11, 1882) the results of his experiments upon the production of this phenomenon. He finds that, when pericardial aspiration is excluded by opening the thorax, it persists; it persists, also, when the communication is momentarily interrupted between the right ventricle and the right auricle, and when the ventricular systole is stopped by irritation of the vagus. It disappears when the systole of the auricle is produced by mechanical irritation or other means, and when the systole of the auricle is displaced, so as to occupy a phase of the diastole. The venous pulse is also displaced. All these facts tend to the conclusion that the normal jugular pulse is produced by the systole of the right auricle.—*London Medical Record*, June 15, 1882.

RELATIONS OF GELSEMIC ACID AND ÆSCULIN.—PROF. WORMLEY, in a series of careful experiments, conclusively refutes the assertions of Sonnenschein and Robbins as to the identity of these two principles, and he gives results from which it would appear that in gelsemium poisoning evidence of the poison in the blood may be more readily and fully obtained than in the case of any of the other vegetable poisons.—*Amer. Journ. of Pharm.*, July, 1882.

Acute Dilatation of the Heart.—Dr. M. Heitler has, in recent numbers of the *Wiener Medicinische Wochenschrift*, touched on a subject of great importance. A sudden or rapid dilatation of the heart does certainly occur under many circumstances; but we think it is necessary to draw a distinction between different forms. There is that which happens in connection with many acute exhausting diseases, such as puerperal fever, typhoid fever, pneumonia, and so forth; and of this nature, or something akin to it, is probably the dilatation which is met with in chronic anæmia. In all these cases there would seem to be undoubted change in the structure of the cardiac muscular walls. But the question is whether we cannot have a dilatation of even more rapid arrival, and which, consequently, can hardly depend on universal softening of the heart's musculature; whether, in fact, "idiopathic dilatation" can occur. Dr. Heitler seems to have observed cases which must come under this division. He talks very confidently of rapidly appearing and as rapidly disappearing enlargement. This he has demonstrated in chronic valvular disease. We are inclined to agree, and think that the remarkably sudden variations in the health of sufferers from chronic cardiac maladies may here find an efficient explanation. Truly acute dilatations of the heart are believed to occur in soldiers during campaigns, and in persons strenuously exerting themselves physically. Dr. Heitler has no experience of such cases. Some authors have taught that such rapid enlargements may ensue on nervous exhaustion, resulting from debauchery and sexual excess. It is possible also that the sensations and illness of amateur mountaineers may be due to the same state. To the symptoms, physical signs, and differential diagnosis of dilatation, Dr. Heitler adds no new knowledge. In treatment, great confidence is placed in digitalis. Further, Dr. Heitler believes that percussion, such as is practised in ordinary physical examination, is capable of bringing about a diminution in the size of the heart. If such occurrences do happen, then it would seem quite certain that we have to do with a reflex action; and inherently there is no improbability. Goltz long ago showed that the frog's heart could be stopped in diastole by tapping the epigastrium, and why should not a contraction be brought about in a reflex manner? Moreover, it may be that any external application whatsoever, such as mustard plasters, act in this manner. We have not yet got at the bottom of reflex actions as a mode of treatment, and we can heartily recommend our readers, if they have not already done so, to study Dr. Lauder Brunton's article on this subject. On so-called "idiopathic dilatation," authors' beliefs are still conflicting. The subject has been treated very fully, indeed, by Seitz, who strongly urges the fact of its occurrence. Schrötter holds the opposite view.—*Medical Times and Gaz.*, July 1, 1882.

A Convenient Method of Demonstrating the Bacilli of Tubercle in Sputa.—Baumgarten gives the following method of staining tubercle bacilli, as easier and more expeditious than those recommended by Koch or Ehrlich. Dry preparations of the tubercular sputa are prepared according to Koch's or Ehrlich's method, and moistened with a very dilute solution of potash; the bacteria can then, without further treatment, be readily detected with a power of 4–500 diameters. Slight pressure on the cover slip will serve to bring them out more clearly. In order to distinguish the bacilli of tubercle from other species, the cover slip is removed from the slide, and laid to one side until the moisture on its under surface has dried off; it is then passed two or three times through the gas flame, and then moistened with a drop of dilute anilin violet or other nuclei-staining anilin color. Now, under the microscope, the putrefactive bacteria are stained a deep-blue, while the tubercle bacilli remain perfectly colorless, as when in the potash solution. The entire process need only require ten minutes, and is, therefore, to be recommended for general use.—*Centralb. f. d. Med. Wissen.*, June 24, 1882.

Treatment of Hemorrhage from the Palm.—Dr. Randolph Winslow gives the following as expressing his conclusions from a study of this subject:

1. Hemorrhage from the palm should be treated by ligating or twisting the bleeding vessels *in situ*, when this can be done without undue disturbance of the tendons and other tissues.

2. This being impossible, compression should be applied in the wound by means of a graduated compress or conical cork, flexion and pronation of the arm being also employed, or the hand may be bound tightly over a ball of wood or cord.

3. Acupressure may be used to the radial artery, but it is not safe to compress the ulnar in this way, as the nerve is in close proximity on its inner side.

4. Other measures failing, ligation of the main vessels should be performed.

5. Owing to the frequent anomalies of the brachial artery, it is better to ligate the radial and ulnar immediately above the wrist, than to tie the brachial itself.

6. The hand should be wrapped in cotton wool, fixed upon a splint, and placed in a sling.—*Maryland Med. Journ.*, July 1, 1882.

Intra-cranial Disease and Choked Disk.—Dr. Edward G. Loring contributes to the June number of the *New York Medical Journal and Obstetrical Review* an article on the nervous connection between intra-cranial disease and choked disk, the conclusions of which are: 1. That the vaso-motor theory, as advanced by Benedikt, is not sufficient to explain either the mode of transmission of the morbid irritation within the head, or the resulting neuritis optica. 2. That the irritation is conveyed, not by the isolated fibres of the sympathetic system, as stated by Benedikt, but through the agency of the trigeminus. 3. That choked disk or papillitis, in connection with brain disease, is the expression of an irritation or compression of certain intra-cranial fibres of the fifth pair which preside over the blood supply of the disk and neighboring parts, and also maintain the healthy processes of waste and repair of the tissues themselves. This being so, he adds, the same analogies and distinctions between "irritation" and "inflammation" can be made here as with sympathetic ophthalmia, so that here, as well as there, the irritation may exist as such for an indefinite time, or may so reduce the vitality and resisting power of the tissue of the disk and surrounding parts as to develop gradually, or explode suddenly, into an actual inflammation—that is, into a neuritis. The immediate and exciting cause of this neuritis may be either an external one, such as exposure to cold or heat, over-exertion, either mental or physical, or, indeed, too much exposure to the light, the effects of which, under the weakened condition of the organ, may be looked upon as a "traumatism;" or the exciting cause may be an internal one, such as some irritation from the condition of the blood and circulating fluids, either chemical or mechanical, either local or general, which insufficient in itself to produce any bad effect upon a normal disk, may yet be just sufficient to produce a condition of inflammation in a part that is weakened and irritable.

Antiseptic Nephrectomy by Abdominal Section; Recovery.—Mr. F. B. Archer reports the following case: M. E. A. L——, a widow, aged fifty, was ad-

mitted into the General Hospital, Bridgetown, Barbadoes, West Indies, on September 13, 1880, under my care. She had had five children. The menses stopped about eight years ago, soon after a fall, which fractured one of the lower ribs on the right side. While ill in bed, suffering from this, she observed a lump about the size of her fist on the right side of the bowels. This lump has never disappeared, but has slowly grown to its present size. It has caused her no particular trouble, but she has lost flesh. Her appetite and general health are good. She has never been tapped. Ten months ago she was in this hospital, and an ovarian cyst was diagnosed, and an operation advised. This she declined, and returned home. She now begs to have something done. Urine contains a little albumen. On microscopical examination no casts are seen. Temperature normal.

On September 14th she was put under chloroform and then ether substituted. Under a spray of carbolic acid an incision was made and a good many adhesions broken down. The cyst seemed matted to the right kidney, and on attempting to clear it the weight of the cyst tore the kidney, and considerable hemorrhage occurred. A clamp was put on, a ligature applied, and the kidney and tumor removed. It contained eighteen pints of fluid, and the cyst itself weighed five pounds. The patient was in a great state of collapse. A drainage-tube was inserted and the wound closed. She vomited five times after the operation, complained of great shortness of breath and pain in the head.

On March 14, 1881, she left the hospital quite well. By the last account she was enjoying good health.

Mr. Knowsley Thornton, through whom the notes are forwarded for publication, remarks that this is one of the best cases of nephrectomy yet published, due regard being paid to the quantity of fluid contained in the cyst, and the weight of the latter, the age of the patient being also taken into consideration. Convalescence, however, was very slow.—*Lancet*, July 1, 1882.

THE ABSORBENT ACTIVITY OF THE STOMACH.—A recent number of the *Berliner klin. Wochenschrift* contains an article by Prof. Penzoldt and Dr. Faber (Erlangen), which is an attempt to place at our disposal a new means for diagnosis of diseases of the stomach. The observations were made with the idea of determining whether the activity of absorption of soluble substances varied in any regular manner with different affections of the stomach. The investigations were conducted thus: The observed swallowed a gelatine capsule loaded with solid iodide of potassium, which when it arrived in the stomach was there dissolved and absorbed, and partly reappeared in the secretion from the salivary glands. Some saliva was then tested at intervals by means of starch papers and fuming nitric acid. At first a red, later on a blue, coloration was developed. In healthy subjects from seven to fifteen minutes elapsed ere the blue color was fully obtained. Some experiments on sufferers from (1) ulcus ventriculi, (2) dilatation of stomach, and (3) ill-defined gastric disorders, were made, and the results compared with those got from healthy individuals. So far the results are of no practical value.—*Med. Times and Gazette*, June 24, 1882.

PAROXYSMAL HÆMOGLOBINURIA.—BOAS (*Centralb. f. d. Med. Wissen.*, No. 20, 1882) reports a case of paroxysmal hæmoglobinuria, and deduces from its study, and of two other cases previously published, the following conclusions:

1. Paroxysmal hæmoglobinuria is a distinct disease, *sui generis*, and can be sharply defined from other forms of hæmoglobinuria.

2. The access of paroxysmal hæmoglobinuria is always attributable to the influence of cold, especially on exposed parts.

3. The intensity estimated by the coloration of the urine and the general symptoms, is directly proportional to the severity and duration of the chilling.

4. The spontaneous attack and those produced experimentally, are absolutely identical.

5. The fundamental change lies in the destruction of the red corpuscles with the passage of the hæmoglobin into the plasma; the general symptoms are only the consequence of this alteration.

6. This distinction is limited to the parts directly exposed to the action of the cold, though, of course, the products of disorganization are carried to all parts of the system.—*Gaz. Méd. de Paris*, June 10, 1882.

EXAMINATION OF THE EAR.—M. GEILÉ (*Progrès Méd.*) has made an experiment of great clinical value; it permits, in certain cases of defective hearing, to locate the lesion and to recognize abnormal action of the stapes and of the apparatus of accommodation. A vibrating tuning-fork is placed upon the frontal eminence of the patient; in his ear is fixed a tube of rubber whose other extremity, closed by a diaphragm of gold-beater's skin is placed to the ear of the observer; this otoscope has inserted at its middle an insufflating bulb.

The apparatus being arranged, the vibrations of the fork follow the cranial bones and are transmitted to the tympanic membrane. The patient perceives a sound which is transmitted by the vibrations of the tympanic membrane and of the air of the tube to the ear of the observer. If now, by the aid of the bulb, the tension in the tube be augmented, that is, if the membrana tymyani of the patient be compressed, his accommodative apparatus, which has lost its integrity, will perform its functions abnormally, the stapes will penetrate more or less in the fenestrum ovale and the sound of the tuning-fork will no longer be the same for the patient and for the observer; the lesion can be immediately localized in the apparatus of accommodation.—*St. Louis Medical and Surgical Journal*, July, 1882.

STRETCHING THE INFRA-ORBITAL NERVE.—COPPEZ (*Ann. d' Oculistique*, Feb. 1882) succeeded in curing a neuralgia of twenty years' duration by stretching the infra-orbital nerve. The neuralgia had been periodic for fifteen years, but for the last five had been almost continuous, and entirely interfered with work. The supra-orbital was also affected, apparently as severely as the infra-orbital, and it was intended to stretch it as well if the first stretching had not succeeded. Immediately after the operation the zone comprised between the nose and middle of the cheek, the half of the upper lip, and the mucous membrane covering it, were completely anæsthetic. The sensibility began to return three days afterwards, and was complete after five days. A little more than two months had elapsed since the operation, without the return of the slightest pain.—*Edinburgh Med. Journ.*, April, 1882.

FIRST CASE OF GASTRIC RESECTION FOR CANCER OF THE PYLORUS PERFORMED IN ITALY.—This operation was performed at the Surgical Clinic of Genoa, on June 14, 1882, by PROF. AZZIO CASELLI, upon the diagnosis of Prof. Maragliano, of "partial stenosis of the pyloric orifice, the result of a carcinomatous neoplasm." The operation was completed in two hours. The elliptical mass removed measured four and three-quarters by four inches. The woman died of shock on the evening of the day of the operation.—*L' Independente*, July 5, 1882.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE, ... $5.00.

SINGLE COPIES, ... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made at the risk of the publishers, by forwarding in REGISTERED letters.

Address, HENRY C. LEA'S SON & CO.,
NOS. 706 & 708 SANSOM STREET,
PHILADELPHIA, PA.

SATURDAY, JULY 29, 1882.

CHOLERA INFANTUM.

As the season for cholera infantum is at hand, it may be useful to lay before our readers some recent experiences in its treatment. Certain points in its pathogenetic development require statement as a motive for the proposed therapy. The influence of diet, especially the ill-effect of a diet largely composed of starch, is too well known to require further expression. But behind and beyond the personal hygiene of the child, there is an important factor which has been entitled "*civic malaria*"—the sum of those causes of pollution arising out of the evil hygiene of towns and cities.

The mechanism of those forces by which cholera infantum is produced is probably as follows: The bad air (germs?) depresses the function of the splanchnics, the inhibiting nerves of the intestinal canal, as the pneumogastrics are for the heart. Prevost demonstrated that ablation of the spheno-palatine ganglion caused a profuse outpouring of serous fluid from the Schneiderian mucous membrane. The depression of the splanchnics probably has a similar effect on the vessels of the intestinal mucous membrane. This disturbance must necessarily be aided by the fermentation of the starchy aliment, taken in excess. High febrile heat and an algid condition will follow the former at the onset of the disease, the latter after persistent outpouring of fluid from the intestinal mucous membrane. The obvious indications are:

To check fermentation, and to destroy the minute organisms or germs on which every fermentation must depend for its development;

To allay irritation of the end organs of the splanchnics in the mucous membrane;

To arrest the outward osmosis from the vessels;

To lower the febrile temperature, and to remove the algid condition.

These indications must be grouped to be dealt with effectively. The three first given must be considered together as objects to be accomplished simultaneously. To stop fermentation by destroying the organisms necessary to the process, involves under these circumstances the use of remedies to restore the functions of the splanchnics. A most useful agent to check the nausea and vomiting is carbolic acid, which may be given in an emulsion with bismuth and a little glycerine. Remarkably good results are obtained from the use of potassium bromide in many cases, if given early enough. Nitric acid, well diluted in small doses, frequently repeated, is an efficient remedy in other cases. In still others, pure Cognac brandy renders an incontestable service. Calomel in minute quantity—from $\frac{1}{20}$ to ^{1} grain—has a place in the treatment of nearly all cases. Are there any definite indications for the employment of these remedies? We believe there are. Carbolic acid alone, or mixed with bismuth, is the appropriate remedy when there is a high degree of irritability, food being rejected as soon as swallowed, or in those cases characterized by the rapid fermentation of the foods in the stomach, resulting in the production of acid. Bromide of potassium is particularly indicated when, with high irritability of the stomach, there are restlessness, wakefulness, twitchings of the muscles, and fever. Whilst the bromide does not materially modify the morbid condition of the stomachal and intestinal mucous membrane, it does allay the irritation of the splanchnics and of the nervous system generally. Nitric acid is remarkably useful when the stools are acid, watery, and without any undigested aliment. It stops the fermentation which produces the acid, and it stimulates the flow of bile. It does more; it solicits the osmosis of the alkaline constituents of the blood into the intestine, and thus restores the proper alkalinity of the intestinal juices. Those who find it difficult to comprehend such an action will be enlightened by a study of the laws of diffusion or osmosis.

Brandy to be useful must be administered freely. It is not as a stimulant merely that it is to be given in this malady. Alcohol is a powerful antiseptic; by its oxidation, force is evolved; and brandy contains astringent matters. It is indicated when the depression is pronounced, when the derangement in the digestion and assimilation of food is due less to the deficiency in the juices, than to the depression in the function of the splanchnics. Brandy, of course, increases in importance as a remedy with the approach of the algid condition.

The *rôle* of calomel as a remedy has been warmly

discussed. Correct notions as to its action, and its proper place as a remedy, are gradually crystallizing out of the mother-waters of experiment and clinical observation. Formerly, the central idea of its administration was "to alter the secretions," this phrase including the biliary and intestinal. Without occupying space in discussing controverted questions, when we have room for merely a dogmatic statement, we will give an expression to the best-founded opinion. Calomel in small doses acts as a *sedative* to the gastro-intestinal mucous membrane, allays vomiting, and checks fermentation. Although the modern view is against the action of calomel on the biliary secretion, it seems to be well established that it does act on the intestinal glandular apparatus, and increases the elimination through them of the products of waste. Judiciously used then, in the small doses above mentioned, there are few cases of cholera infantum in which calomel may not be beneficial.

We have yet to discuss the treatment of the febrile state, and of its corollary, the algid. The condition of the gastro-intestinal mucous membrane precludes the administration of the ordinary antipyretic remedies. In many cases the range of febrile heat is great, the maxima of the thermal range encroaching on the danger line. Indeed, in cholera infantum, it is probable we have to deal with a specific fever. Besides acting on the causes of the febrile heat it becomes necessary to restrain the body temperature within proper limits. The development of hydrotherapy by our German *confrères* has led to a most useful application of the practice to cholera infantum. With the thermometer as a guide, the child should be immersed in water at 95° Fahr., and the bath then cooled to 75°, 70°, or 65°, according to the temperature of the body and the influence of the bath—cooled by the addition of sufficient cold water or of ice. Such is the general idea; our space is not sufficient for details. The time for the repetition of the bath cannot be arbitrarily stated, but it must be determined by the effect produced on the temperature. The influence of the bath is most conspicuous for good. Its value as a remedy for this condition can hardly, indeed, be overestimated.

The algid stage of cholera infantum offers the same difficulty in its management that the corresponding condition in cholera does. As regards the exhibition of alcoholic stimulants, it should be borne in mind that small doses frequently repeated will support the failing circulation, when large doses will have the opposite effect. Belladonna, or its alkaloid, atropia, is a powerful stimulant to the heart, which has been used with advantage in the algid condition. Nitro-glycerine will probably prove useful in the same condition by dilating the peripheral vessels, and thus permitting the heart to work under lessened pressure.

We have barely mentioned the subject of alimentation. The character of infant foods, and their relation to the subject under consideration, is too important to be dismissed in a few words. We therefore close the consideration of the medicinal management of cholera infantum, reserving for future discussion the questions connected with food and alimentation.

PRESIDENT GARFIELD'S CASE AGAIN.

The carefully prepared article of Dr. Baker which we publish in this issue constitutes another contribution to the ever-increasing literature of the Garfield case, the surgical problems of which, not only from the fact that they involved an illustrious life and the destinies of a nation, but also from their intrinsic importance, have possessed unusual interest for both the profession and the laity.

Dr. Baker has analyzed, in a painstaking manner, the evidence given at the Guiteau trial relative to the positions of the assassin and his victim, and makes therefrom several deductions as to the probable course of the first and of the second shot, concluding that it was the latter which proved fatal. It is not apparent how this affects the general proposition that a knowledge of the positions of the parties and of the course of the ball, until it struck the eleventh rib, could have been of little value in determining its further direction, or might even have led to an erroneous conclusion. Whatever arguments are urged as to the possibility of inferring the direction of the bullet after its contact with the ribs from its known course before it entered the body, are very much weakened by the extremely erratic course which missiles so often take after impinging upon resistant and resilient bodies like the floating ribs. Whether the President was turning to the left or to the right when he received the fatal wound, and whether it was the first or the second bullet which caused it, are questions of historic interest and also of dispute. We believe, however, that there is no dispute as to the general direction of the ball in its course from the muzzle of the pistol to the wound of entrance. There can be no doubt, and so far as we know it has not been questioned, that if *that* line were continued it would lead downward, forward, and to the left; but that without deflection it would represent the actual course of the ball, or that the surgeons, even if they had been familiar with all the facts which the Government, after the labor of months, and an exhaustive examination of a large number of witnesses, was able to elicit upon the trial, would have been justified in assuming that the missile had proceeded in that direction, we believe to be incapable of demonstration.

Dr. Baker does not allude to the fact that a line carried from the point of fracture in the twelfth rib, through that in the eleventh rib, and prolonged until it reached a point six feet behind the President, would have attained an elevation, which, allowing for all possible positions of the two ribs, would still have been far above the head of the assassin, or, in other words, several feet above the level at which he held the pistol. It is this *vertical* deflection which was described in Dr. White's article—to which Dr. Baker's is a reply—and all the testimony shows that at the time of the second shot the President was still standing erect.

It should be remembered, too, that, apart from these considerations, Dr. Baker's argument as to the surgical value of a knowledge of the positions of the parties depends entirely upon the literal exactness of witnesses who testified after a considerable lapse of time to the minute details of circumstances occurring during a scene of great excitement. If the muzzle of the pistol varied materially from the direction in which he believes it to have pointed, the whole problem from his point of view would necessarily be changed. In view of all the facts that the evidence as to the position of the parties, which was presented to the surgeons called in attendance immediately after the shooting, was that the first shot was the one that took effect, and that at the time the President was turning to the left, it seems to us that there is hardly sufficient basis upon which to build so elaborate a theory as Dr. Baker has presented.

As to the possibility of a diagnosis from the subjective symptoms, there can be no doubt that scores of such "snap diagnoses" were made all over the country, but there is also no doubt that the symptoms, singly or collectively, were insufficient to warrant them. The pains in the limbs—only symmetrical in the sense of being bilateral—were of unequal severity on the two sides, and had largely disappeared on the left side forty-eight hours after the shooting; in the absence of any loss of power, they had little value as a diagnostic sign of spinal injury, and could be accounted for as well without as with such a lesion.

Certainly no conservative surgeon would have allowed himself to be influenced by some of the additional arguments which Dr. Baker advances in support of this theory. Pain on one side of the scrotum; vomiting, extremely common after all gunshot wounds; a thready pulse, indicating hemorrhage, which, as the vessels lie near the spine, must have come, according to Dr. Baker, from that locality; the absence of paralysis; "daily evacuations," etc., can hardly be considered as pathognomonic symptoms of spinal injury.

The exact nature of the change in the splenic artery which led to its rupture, the immediate cause of death, will doubtless always be a matter of conjecture, but in the absence of any more plausible theory, with which Dr. Baker does not seem to be provided, we may assume that it was in one or the other of the ways already suggested in Dr. White's article.

The anatomical point Dr. Baker raises, based on the relative course of the ball and the artery, seems to be well taken. But here, again, he has misunderstood the situation. If the artery had been wounded at the time of the shooting, it does not follow, of course, that the aneurism developed immediately. It might have been the result of slow inflammation of the coats of the vessel. No one supposes that the false aneurism—the actual rupture of the coats of the vessel—took place earlier than about the time the President went to Elberon, or that it "existed eighty days," as Dr. Baker puts it. The reason for this opinion was given in the paper just referred to.

The cases quoted by Dr. Baker, in support of his opinion that the wound was not necessarily mortal, although not new, are interesting, but are not analogous, neither of them having been a *perforating* wound of the vertebra. In the first case, the injury was a penetrating wound, the circumstances of which, in regard to the opening of venous sinuses, the splintering of bone, etc., are always very different from those in which a ball inflicts the additional damage incident to a wound of exit. The clinical history also is very indefinite. In the second case, the wound of the body of the vertebra was merely a groove in its surface, and it may be said in addition, that to diagnosticate the position of a bullet in the left side of the body of a vertebra by digital examination made through a wound on the right of the spine appears to be incompatible with the usual length of the human finger.

Moreover, it has not been denied that a vertebra may be wounded and recovery follow, that a bullet may be imbedded in it, or that its body may be grooved without fatal consequences. Such cases, though uncommon, are not of exceeding rarity. They are by no means parallel, however, with that of President Garfield, in which the body of the vertebra was *perforated*, and it is unquestionable that no authentic instance of recovery after such a wound as this has ever been recorded.

We have been impelled to make this brief review of the points in Dr. Baker's paper, not from any desire to re-open an argument which we had hoped was permanently at an end, but because, recalling with regret the unjust newspaper criticism which has prevailed throughout the country, and, with indignation, the recent indecent tirades in Congress, we feel it our duty, for the sake of medical science

and for the honor of the profession, to take every opportunity of asserting our unchanged belief in the wisdom of the course pursued by President Garfield's surgeons.

SENATOR CAMERON'S JOINT RESOLUTION.

AN interesting correspondence has taken place between the Chairman of the Committee on Medical Legislation of the American Institute of Homœopathy, and the heads of the medical departments of the army and navy, through the medium of Hon. Charles O'Neill, M. C.

The homœopath wrote to ascertain if the Secretary of the Navy authorized any discrimination between the diplomas of homœopathic medical colleges in good legal standing, and "those of the allopathic, or so-called 'regular' school," in the admission of candidates to examination for the medical corps. He also wanted to know if a graduate of a regular medical college who avowed his belief in homœopathy would be considered eligible. He made the same inquiries in reference to the medical appointments of the army.

From Mr. Chandler, Secretary of the Navy, he received a reply stating that no discrimination was made in favor of or against any school. "The only requirements of the department are that a candidate, in addition to his moral and physical qualifications, shall possess the necessary professional and literary knowledge to enable him to pass the established examination." Certainly a most cautious and conservative answer, but one which, if we read between the lines, offers very little hope to the discontented applicants. We believe, after some opportunity of careful observation, that any fair-minded and impartial board of examiners acquainted with the exigencies of the service, and knowing the responsibilities which may at any time devolve upon the naval surgeon, would be compelled to reject, for lack of "necessary professional knowledge," applicants who had received their medical education at homœopathic colleges.

This assertion, which we make unqualifiedly, is founded not on a disbelief in therapeutic dogmas, but on positive knowledge of the radical defects in the character and methods of teaching the elementary principles of medicine—anatomy, physiology, etc.—which prevail in such institutions.

Whether it is proper to place the lives of the officers and men of our army and navy in the care of irregular practitioners is another question, and in this respect the very manly and straightforward letter of Surgeon-General Barnes meets with our entire approval. After calling attention to the fact, so commonly misunderstood by the laity, that the term "regular," as applied to a medical school, has no relation to its legal standing, but merely indicates that its teachings are not confined to the doctrines of any particular sect, he adds that the knowledge which a medical officer of the army should possess to enable him properly to perform his duties can only be obtained at a regular medical school, and that "it is not considered worth while to waste the time of the army medical examining boards or to induce young men to incur useless expense by extending invitations to appear before such boards to those who cannot furnish evidence that they have at least had an *opportunity* to obtain the knowledge required." An acquainance with the dogmas of any particular system of medicine would not prevent a candidate from being admitted, but an avowed adherence to some one of them would prove a bar to his admission, and we hope will always continue to do so.

The resolution of Mr. Cameron, however, to which we referred in our last issue, and which is so admirable an illustration of the depths of ignorance to which the "practical politician" descends when he permits his statesmanship to venture beyond the arrangement of primaries and the management of conventions, points in another direction. It must be humiliating to the petitioner of a "pathy" to find that in the minds even of their advocates no distinction is made between them and the rest of the army of "pathies"—eclectics, Thomsonians, mesmerists, botanists, and all the other quacks who have succeeded here and there throughout the country in obtaining legislative recognition and in establishing "colleges." Mr. Cameron has doubtless no serious idea that his resolution will prevail; but if he hoped by it to secure the votes of these irregular practitioners for himself or his candidates, he should have been more select in his bestowal of privileges. At any rate, each of the "exclusive schools" will be able to excuse its failure, as Falstaff did his many defects: "Company, villanous company, hath been the spoil of me!"

SUMMER SANITATION.

IT would be well if all our other large cities should imitate the example of New York. The Board of Health, which has powers granted to few such municipal bodies by our legislators, appoints each year fifty physicians as Sanitary Inspectors, who for five weeks in July and August inspect the tenement houses of the city, report the grossest nuisances to be abated, prescribe especially for the sick children of the poor, and distribute tickets to the excursions given by the various charitable associations.

It would be well too in the interest of the sick children, and especially of sick infants, if the example of the Philadelphia Board of Health were

followed. At their instance the Philadelphia Obstetrical Society formulated a few simple rules for the management of sick infants in hot weather. These suggestions were printed in the newspapers and in cheap pamphlet form, and are distributed every summer in drug stores and through physicians gratuitously to all who would take them. Many a life we doubt not has been saved by their observance; and many a mother has got her first and much needed lesson in hot weather hygiene from these admirable rules.

We note also with pleasure the sanitary work of the Citizens' Sanitary Society of Brooklyn, and the New York Association for the Improvement of the Condition of the Poor. The recommendations they have made for the removal of sanitary evils are admirable, and the defects and abuses they have revealed have been surprising. Most surprising of all is the statement made by Mr. George C. Booth at the recent sanitary meeting at Greenwood Lake, that "the wealthiest and most prominent church corporation" in New York City has scores of tenement houses which are in the foul condition he describes so vividly, and that the church corporation exacted last May ten and fifteen per cent. increase of rent under pain of eviction, instead of spending some thousands out of its millions in remedying such monstrous evils.

SOCIETY PROCEEDINGS.

COLLEGE OF PHYSICIANS OF PHILADELPHIA.

Stated Meeting, June 7, 1882.

W. S. W. RUSCHENBERGER, M.D., PRESIDENT, IN THE CHAIR.

DR. JOHN M. KEATING, read a paper on *The Presence of the Micrococcus in the Blood of Malignant Measles; its Importance in Treatment.*

He said: I propose to present for your consideration this evening the report of a recent epidemic in the Children's Asylum of the Philadelphia Hospital. The ward in which the disease first showed itself contained children between the ages of two and three years; some of them had been deserted by their mothers, and others had been placed there temporarily whilst the mothers were employed in duties about the establishment. For the most part, these children presented a fair appearance of health; they were seemingly well nourished, of good development, though probably they would have been classed as "strumous," if their large features and tendency to glandular enlargements and eczematous eruptions had received careful attention. Together with all children of this class living in asylums, they certainly presented an open field for the production of those complications that are usually such fatal attendants upon measles.

Dr. Formad examined almost daily the blood of each little patient, and together we noted the presence of micrococci in the malignant cases, and their absence in those of mild type. We entered this study with no preconceived views; the rapidity with which this exceedingly fatal epidemic came upon us, necessitated careful study in order to attempt, if possible, to discover its cause.

CASE I.—J. F., aged two years and three months, was taken sick April 12, 1882. There had been no cases of well-defined measles in the house at that time, although it was epidemic in the city. The child had a sore throat, some cough, with fever. The throat eruption was punctated and well marked. The child died in convulsions April 15, 1882.

Autopsy.—An ante-mortem (chicken-fat) clot was found in the right heart, extending into the pulmonary artery. There was great systemic venous engorgement. A decided staining was noticed upon the cadaver, especially about the temple, which caused the remark that the disease was probably one of the exanthemata. This child had been placed upon carbonate of ammonium, quinia, and digitalis; had had bromide of potassium, hot baths, and stimulants in small quantities.

CASE II.—M. J., aged three years and five months, was taken sick April 9, 1882. A slight eruption on the face was noted April 11, 1882; the next day the eruption was complete over the entire body. In this case the eruption was irregular, was decidedly that of measles, but of malignant type. Still she did well until April 17, 1882, when suddenly the breathing became harsh, and pulse was rapid. At 4.30 P.M. had an attack of suffocation with rapid, feeble pulse. There was general venous engorgement, the face and lips were purple; pulse growing more rapid. Hot baths with mustard and frictions were used, and carbonate of ammonium and digitalis given. It was suggested to bleed in this case, but the evidences of heart clot were so marked, and the child had exhibited so many evidences of malignancy at the onset, that baths were used instead. April 11, 1882, at 3 A.M. she was still growing worse despite treatment, and shortly after had a violent convulsion and died.

There was no autopsy permitted.

CASE III.—A. G., æt. sixteen months. Took sick April 15, 1882.

April 16th had prodromes of measles. The temperature and pulse ran as follows:

16th.— P.M. 102°.
17th.—A.M. 101°; P.M. 103°; pulse 180.
18th.—A.M. 102°; P.M. 103°; pulse 180.
19th.—A.M. 101°; P.M. 102°; pulse 160.
20th.—A.M. 101°; P.M. 102°; pulse 148.
21st.—A.M. 100°; P.M. 100°; pulse 180.

In this case no defined eruption appeared on the body, although there was a decided papular eruption on the uvula and anterior half arches of the throat. Whilst showing this case to the class we noted streaks of grayish membrane in the fauces. The child had decided bronchitis, and the voice showed that the laryngeal mucous membrane was also affected. This child was not at that time very ill. There was no question in our minds at the time that it was affected severely by the measles poison; that it was, in fact, another malignant case. It was carefully watched, the nourishment regularly given with quinia and iron daily, as was customary in all the cases.

On the 21st, the breathing was noted as peculiar (I shall describe it hereafter). An emetic was ordered of ipecac, fearing an accumulation of mucus from the bronchitis present, and also carbonate of ammonium and digitalis and hot foot baths were given. The child's intelligence seemed good, and it will be noted that the temperature was but 100°, while the pulse was 180.

At 8 P.M. a second attack of suffocation occurred, and the child died in violent convulsions. The venous engorgement was very marked.

Autopsy.—Ten hours after death. *Heart:* left side and valves all normal. *Right side:* a large ante-

mortem clot filling the cavity of the right ventricle, and extending into the auricle; a clot was also seen in the pulmonary artery. *Lungs:* left, normal. *Right lung:* at the base of this lung the lesions of pulmonary congestion were seen, especially where the lung approximates the diaphragm. *Intestines:* slightly congested and hyperæmic. *Mesenteric glands:* enlarged and infiltrated by simple congestion. *Kidneys:* normal. *Blood:* taken from the heart cavity as soon as it was opened and examined, showed micrococci in the liquor sanguinis and *in the white blood corpuscles.*

CASE IV.—J. F. McH., æt. 23 months. This child had a typical attack of measles. The eruption was rapidly disappearing, and desquamation had set in. April 21st the bronchitis seemed to be aggravated, the respirations were 36, and expirations seemed unusually prolonged. The breathing was noisy; the heart's action was rapid, pulse 148. Suddenly, in the evening, an attack of suffocation came on, which was relieved by an inhalation of nitrite of amyl. On the morning of April 22d the heart was beating 168; the venous engorgement was very marked, the jugular veins standing out like whip cords, the respirations were from 36 to 40, but the temperature was 99°. I saw the child at this time, and noted the gasping breathing, the feeble pulse, and the tumultuous action of the heart. There seemed to be capillary spasm, judging from the gasping breath, the imploring look which the child gave to all its attendants, and we at once gave an inhalation of *nitrite of amyl.* In a few moments it seemed relieved. The administration of carbonate of ammonium, digitalis, hot baths, etc., was rigidly adhered to. The child seemed confortable until 4.30 P.M., when it had another attack of milder character, though longer duration, and in it finally died of convulsions. It was observed, says Dr. Campbell in his notes, that the convulsion was not as severe as in the previous cases.

Autopsy, twenty hours after death.—Eruption not well marked. *Heart:* right ventricle contained a small ante-mortem clot. This clot was in the cavity of the ventricle, and did not involve the valves, either tricuspid or pulmonary. The left side of the heart was normal in every respect; contained no clot. *Lungs:* normal, with the exception of hypostatic congestion at both bases. The pulmonary and costal pleuræ of the left side were inflamed and adherent in some places. *Trachea:* inflamed and containing a tenacious mucous secretion. *Larynx:* inflamed and hyperæmic. *Liver:* normal. *Intestines:* Peyer's patches and the solitary and agminated glands infiltrated and hyperæmic. *Mesenteric Glands:* enlarged and infiltrated, they were about the size of a grain of corn. *Kidneys:* normal. *Spleen:* amyloid bodies enlarged until they presented almost the appearance seen in a tubercular spleen. *Blood:* taken from heart as soon as punctured. Micrococci were found in the liquor sanguinis and *in the white blood corpuscles, and they were mobile. In the corpuscles they were seen in great numbers in active movement of a vibratory or whirling character, and they appeared to have devoured the white cells.* No bacilli were seen.

CASE V.—J. McG., æt. 26 months. Ordinary case of measles. The eruption had disappeared on or before April 15th. *April 22d.*—Child restless; marked bronchitis; cough paroxysmal upon waking, especially after excitement; mucous râles coarse, and fine throughout lungs posteriorly; throat congested, and saliva at times tinged with blood. At this date the breathing was noted as noisy. Pulse 144, respiration 32, temperature 100°.

23d.—Mucous râles becoming general, and not limited to areas as heretofore; pulse 152; respirations 34; temperature 101°. In addition to the tonic and stimulating treatment, mustard poultices were applied to thorax, and hot baths frequently given. Carbonate of ammonium was given now, gr. ij, ever hour, and bisulphate of quinia by suppository, gr. ij, every three hours. In addition to this the child was given, as were all the others, milk and lime-water, beef tea, etc., at frequent intervals. In this case the frequent administration of small doses of syr. ipecac. was resorted to in order to relieve the secretion, which was abundant and tenacious.

23d.—Evening. Pulse was rapid, 160 to 170; temperature 102½°; breathing becoming labored and gasping (fish-like); venous stasis was becoming more marked. Increased the whiskey to about one ounce a day. The attacks of suffocation continued paroxysmally, the jugular veins stood out like cords at times. *Nitrite of amyl* gave immediate relief, but relapse soon followed; it was always followed by free emesis, which seemed to be in itself beneficial. About midnight a severe paroxysm came on, and with it a convulsion in which the child died. It had been suspected for some time that a heart clot was present. After death the venous engorgement was even more marked than before. This little patient was the first case whose blood Dr. Formad examined during life. The view of the fluid was photographed; *micrococci were found in great abundance, acting especially on the white corpuscles.* The blood was examined very shortly before the child's death, when the symptoms of heart clot had been fairly established, and the case declared hopeless.

Unfortunately, no autopsy was permitted in this case.

CASE VI.—F. M., aged 2½ years. This case ran a course as did the others, and I will only occupy time with a description of the post-mortem appearances. Eruption well marked on mucous membrane of buccal cavity, not so on cutaneous surface. Upon laying thorax open, lungs found to be anæmic, as far as arterial circulation was concerned, but dammed up with venous blood. *Heart:* normal in size and weight.

Right side contained a clot extending along the pulmonary artery for some distance; it was chicken-fat in consistence. *Left side:* normal. *Spleen:* congested; weight, four ounces. *Intestines:* along the small intestine could be seen a few Peyer's patches inflamed, and well outlined against the comparatively normal gut. The mesenteric glands presented a very good example of enlargement and infiltration; they looked like so many peas scattered throughout the mesentery. *Liver:* normal. *Kidneys:* normal. *Brain:* not examined. *Blood:* taken from heart cavity as soon as it was open, showed micrococci in the liquor sanguinis and *in the white blood corpuscles in abundance;* they were not mobile. A number of zoöglœa masses were seen.

CASE VII.—C. M., aged two and a half years. The eruption in the throat of this child was very well marked. A few crescentic points appeared in the temples, and the case rapidly developed malignant symptoms.

April 21.—Slight grayish suspicious patches of membrane are seated in the throat. The child is hoarse and there is much bronchitis.

22d.—Pulse rapid; respiration 28; breathing irregular. There is great general venous stasis, the skin dark and mottled. Dr. Formad examined the blood microscopically, and found it full of micrococci. He took a specimen sample for photography. Prognosis very unfavorable, as the child has fluttering heart and gasping breathing. Hot baths had been used freely with no success, so also salicylic acid, which had been suggested early in the disease. After consultation with Dr. Formad, the account of which I incorporate in the

summary, it was concluded to give at once ʒij of whiskey, and repeat it every hour; milk was continued as the only other food.

24th.—Pulse, 144; temperature, 101°; respiration, 48. Circulation much improved. Venous engorgement relieved; breathing greatly improved. The child continued to improve during the day. At the end of the twenty-four hours it had taken six ounces of whiskey, and yet it showed no effects of alcoholism. At noon the pulse was 140; respiration, 36. 6 P.M. pulse, 132; respiration, 32. 11 P.M. pulse, 122; respiration, 26, and regular; breathing easy, though somewhat noisy, but not harsh.

25th.—A.M. temperature, 98°; pulse, 128; respiration, 26. P.M. temperature, 98°; pulse, 108; respiration, 24.

26th.—A.M. temperature, 98°; pulse, 96; respiration, 22. P.M. temperature, 98°; pulse, 104; respiration, 24. The respirations remained regular, and the child continued to improve. After the examination of the blood on April 30, owing to the relative increase of the white corpuscles, it was decided to give Fowler's solution of arsenic, gtt. ij, three times daily. The large doses of whiskey were kept up for three or four days, and gradually diminished.

I give Dr. Formad's reports, which he kindly wrote out for me, of the microscopic examination of the blood in the above case (examination made with a one-sixteenth immersion lens).

Examination April 22, 1882.—Blood full of micrococci (sphero-bacteria), affecting many of the white blood-corpuscles; also a large quantity of these fungi free and in various forms of grouping, mostly in zoöglœa masses. White blood-corpuscles are in increased quantity; precipitation of fibrine excessively marked under the glass.

24th.—Micrococci present, but in diminished quantity; white blood-corpuscles less affected; precipitation of fibrine less marked.

26th.—Micrococci very marked, yet principally in zoöglœa masses, and free in serum, but not affecting the white corpuscles, although the latter are in increased quantity; fibrine not noticeable.

30th.—Micrococci present; white blood-corpuscles still in excess, but not affected by micrococci. Red blood-corpuscles not readily forming rouleaux, having partly lost their biconcavity.

May 3.—Micrococci present in diminished quantity. White blood-corpuscles diminishing in quantity.

18th.—Still some few micrococci present; blood otherwise appears normal.

Case VIII.—J. W., æt. eight months. *May 13.* P. M. Eruption appeared on fifth day. The temperature ran as follows:

May 13.—P. M. 100⅗°. A fever mixture was given during the day. Quiniæ et ferri citratis, gr. ij, every three hours.

14th.—A. M. 101⅖°; P. M. 102⅗°.

15th.—A. M. 101°; P. M. 103⅖°.

16th.—A. M. 101⅖°; P. M. 104°.

17th.—A. M. 101°; P. M. 102⅗°.

18th.—A. M. 102°; P. M. 103⅖°. The eruption fading, but leaving a purple stain and mottled appearance of skin. Catarrhal pneumonia or collapse probably exists, as the bronchitis is very extensive, the *râles* numerous, and subcrepitant. The blood examined under the microscope *shows micrococci in the blood corpuscles, but none free in the field. They are seen in great numbers.*

19th.—A. M. 100°; P. M. 103°. For the past two hours the child has been very restless, the breathing rapid and labored, and also spasmodic. No membrane on tonsils or fauces. Heart's action very rapid, venous stasis marked especially in the jugular veins. Gave hot baths (says Dr. Campbell's notes), and covered him with blankets, with some relief. Increased the whiskey to ʒij every hour. In the evening gave an emetic. The child at night was breathing easier; friction sounds heard.

20th.—A. M. 103⅘°; P. M. 102°. At times the strangulation would seem imminent. The venous engorgement increased, and the child died in convulsions on the morning of the 21st. The post-mortem examination showed pneumonia and pleurisy with effusion.

21st.—A. M. 105°, death.

The following eight cases were all taken sick at once, and I shall simply give a general statement of them for the purpose of especially calling attention to the case of W. L.

J. J., aged four years; W. L., aged five years; E. C., aged three years, catarrhal bronchitis; W. W., aged three years; C. B., aged two years, catarrhal bronchitis; J. W., aged five years; J. D., aged five years; L. K., aged five years.

Of these *eight*, seven presented severe but nevertheless typical examples of measles, and their blood was carefully examined by Dr. Formad and found normal. The case of W. L., who was taken ill at the same time as the others, showed from the onset a malignant tendency, giving a record such as I have already described. Dr. Formad gave me the following as the result of the examination of the blood in this case, and I had frequent occasion of examining it with him myself. Let me say that as soon as the presence of micrococci was established, the child was placed upon ʒij doses of whiskey every hour. Quiniæ et ferri citratis in citric acid, gr. ij, every three hours, friction to the extremities, and warm baths, with milk and beef-tea.

April 22.—A few micrococci seen in the field.

26th.—Again noted.

30th.—Micrococci still present, white corpuscles increased and marked precipitation of fibrine. *None were noted as having penetrated the corpuscles;* those that were found were simply in the serum. This child recovered, though every indication gave a very unfavorable prognosis.

In presenting this detailed report I desire to call especial attention to the following points, viz., the microscopic examination of the blood and the constant association of *micrococci* with the general manifestation of malignancy (a condition already well known), and the gradual but positive amelioration of all bad symptoms by treatment which was directed to the micrococci as the *fons et origo* of trouble (this, I believe, for the first time exhibited).

It will be noted that the *post-mortem* examinations of these cases showed more or less simple pulmonary congestion, and at times simple enlargement of the glands, but usually so circumscribed as to preclude the possibility of its being the immediate, or even remote, cause of death. Again, the mode of death was peculiar; the fatal signs came on suddenly and with frightful intensity, the gasping breathing, the frantic efforts to obtain air (or really to aerate the blood), the imploring look, with consciousness not impaired, seemingly unduly acute, until the final convulsion or gradual cyanosis brought the end. The turgid veins, the occasional venous engorgement, the feeble pulse, and the fluttering heart pointed unmistakably to but one cause, the gradually forming right-sided heart-clot, and the *post-mortem* appearance, as these notes show, gave us a large, tough, chicken-fat clot, obstructing the venous circulation, firmly planted in the right heart and its tributaries. One of the earliest symptoms of this impending danger was undue rapidity of respiration. The child seemed to be doing well, its eruption irregular, probably incomplete, or dark and mottled, and in blotches, when attention would be called to the great

rapidity of respiration, with a peculiar gasping inspiration, fish-like in character. The other fatal symptoms would follow rapidly, and within twelve hours the child, despite carbonate of ammonium, warm baths, digitalis, etc., would die of heart-clot. What caused this?

In a short paper which appeared in the *American Journal of the Medical Sciences* for January, 1882, I gave the experience of a number of cases of diphtheria, scarlet fever, and measles, and then attributed the condition to an increase of fibrine due to the rapid tissue-changes and the malignancy of the type of disease, and urged the importance of pushing an alkaline treatment from the start.

The microscope has shown here that something more is associated with this condition.

The moment that symptoms of malignancy, viz., dark eruptions, illy-defined crescents, delayed and imperfect appearance of the eruption, with feeble circulation, high temperature, and pharyngeal false membrane appear, the examination of the blood showed *micrococci* in abundance in the field. They do not simply lie as impediments to the free passage of blood, though they most undoubtedly do this, and obstruct its passage in capillaries, but they surround the corpuscles, they enter the white corpuscles, and there develop with surprising rapidity, and finally cause some of them to rupture, and their contents will cover the field. Still, if they alone clogged the circulation in the capillaries, caused stasis in the lung, and thereby provoked an accumulation in the already enfeebled right heart, with blood having a tendency to coagulate, the cause of heart-clot alone would seem explained.

We find that they develop with activity when the blood current is retarded, hence we find them spread throughout the heart-clot itself, possibly at times having been here arrested by the obstruction to the flow caused by the lung congestion, known as a frequent complication of these cases, and finally aiding, by a mechanical cause alone, the deposition of fibrine that forms the clot. They do more; they act upon the white blood corpuscles, destroy them in all probability, or, at least, as one of the cases proved conclusively, prevent their change to red corpuscles, and thus the oxygen carriers being either destroyed or reduced in numbers with none to replace them, the tissues retain their detritus for want of carriers to relieve them, and another factor is added to increase mortality.

Granted, then, that the appearance of *micrococci* is coincident with symptoms of malignancy, we must assert that, whether their association be *post hoc* or *propter hoc*, they must have common cause; our treatment receives an impetus in a new direction.

I asked Dr. Formad what, in his experience, most readily checked the development of *micrococci* in his culture solutions obtained from erysipelas, diphtheria, etc.; he answered *alcohol*. Dr. Campbell at once withdrew carbonate of ammonium and digitalis from the treatment for the future, and gave whiskey. Five children had already died with the symptoms I have just described, and the sixth was exhibiting all the malignant symptoms, together with those which experience had taught us came from commencing heart-clot. The child had rapid gasping breathing, was becoming cyanosed, its heart was tumultuous, and the rapid pulse was growing weaker. The instructions were to give *three ounces of whiskey within the next twelve hours*, in frequent and small doses. The treatment was carefully carried out, and the child was saved. In this child *micrococci* were found in abundance in the blood, but none had penetrated the corpuscles, and for a long time the preponderance of white blood corpuscles was noted, which continued until gradually the blood became normal under the use of *arsenic*.

Again, let me illustrate another point. In one ward there were six cases at the height of eruption, I carefully examined, with Drs. Campbell and Markoe, each case. One case was found to be of a malignant type. The child's right cheek was hardened and inflamed, and the mucous membrane showed that glistening surface so manifest in cancrum oris. The breath was fetid; there were cerebral symptoms; and a grayish exudation lined the fauces. We wished to test the microscope; so, without reference to any particular case, we requested Dr. Formad to examine the blood of all. In five the blood showed no *micrococci;* in one a large mass appeared in the field upon the first examination, and this one was the malignant case. This child was placed at once upon large doses of whiskey, and it was also given, in tonic doses, quiniæ et ferri citratis and citric acid.

The *vegetable* acids, especially acetic acid, have also this remarkable effect of checking the development of micrococci in culture solutions; but the mineral acids, also carbolic acid, it is said, have no such action.

The *bichloride of mercury* also possesses this quality to a very marked degree.

Now let me, for a moment, review this subject in the light of treatment, which to us is certainly of greatest importance. We may look at present upon the *micrococcus* as associated with the malignant symptoms of all complications known as "blood-poisoning." It is found in erysipelas, in puerperal septicæmia, in diphtheria, and in malignant measles. Experience has already taught us that alcohol, the vegetable acids, calomel, or corrosive sublimate, are the drugs *per se* in septicæmia.

The action of alcohol and calomel is too well authenticated in puerperal septicæmia to doubt their efficacy.

We know of late how surprising a result will often attend the use of alcohol and *corrosive sublimate* in malignant diphtheria, and also the value of vegetable acids, especially lemon-juice and claret, in this dreaded disease.

My cases simply illustrate one part of the subject. In this recital I do not allude to the other death-producing complications which are so universal. Children with measles will die of cerebral complications, of pneumonia, of enteritis, and entero-colitis—with these we have nothing to do at present. Their treatment will, of course, depend upon the lesions—quinia, opium, hot baths, poultices will all take part.

I have simply brought forward the subject of "blood-poisoning" for your consideration, and as these remarks are based upon the careful study of but one epidemic, they cannot be submitted as conclusive, but simply as illustrative of what may, at some future time, be accomplished by studying, not merely the bacteria anatomically and physiologically, but by experimentation with bactericides as antidotal in their action, in diseases they may cause or complicate.

The conclusions which seem warranted by the statements of this paper, and by observations made in other cases in the Hospital, are as follows:

The *micrococcus* is found in the contents of pustules and vesicles, and also in the blood taken from the measles-papule in ordinarily mild cases, without its being present in the blood taken from the punctured finger. In severe cases, called malignant in this paper, owing to the rapid appearance of morbid symptoms, the blood shows early in the attack numerous patches of micrococcus in the field.

In cases of rapid sthenic disease with high temperature and great tissue change, the evidences of large quantities of fibrine with a tendency to coagulation are manifest. The rapid production of micrococci soon gives the mechanical impediment, and if stasis takes

place from any other obstruction to the circulation, clots rapidly form.

The non-appearance of clots in malignant fevers, attended with fluid blood, such as low forms of typhus, diphtheria, etc., is simply due to the fact that rapid tissue changes have resulted in decomposition, instead of into fibrine-forming substances—no fibrine is formed, hence no clots—but the micrococci are present all the same. These cases are held by some to be the malignant ones, but I think the *foudroyante* character of the others, just mentioned, entitle them to be placed in the same category.

But the micrococcus, if left unheeded, may attack the white corpuscle, as distinctly seen under the microscope, and destroy its contents. The red cells also change in appearance, and finally probably become, to all intents and purposes, useless in the economy. When such a condition is seen by the microscope and found extensive, a fatal prognosis can be given, despite the most active treatment.

In cases where the white blood-cells are as yet unaffected, treatment, when active, will be followed by good results, provided the other complications, as visceral inflammation, etc., are not in themselves excessive.

Alcohol (whiskey in our cases) seems in some way, when given in large amounts, to check the progress of the marauders, to arrest the process of destruction, and, if needful, can be associated with quinia and iron in small repeated doses, digitalis perhaps, and frictions, baths, and poultices, etc. As we have seen, the symptoms presented are contemporary with the changes going on within the blood; they may, *in lieu* of a careful microscopic examination of the blood, be taken as a gauge for treatment; knowing what can and will take place, early active treatment will give the patient some chance for the future.

CORRESPONDENCE.

LETTER FROM BERLIN.

The "Cultures" in the Study of the Acute Infections—The Prevention of Tuberculosis.

HISTORIANS teach us that trivial accidents sometimes determine the fate of empires. No less an influence do they exert at times upon the progress of a science. Mr. Darwin näively tells us himself that he was put upon his train of thought by the perusal of the work of Malthus upon population. What the apple was to Newton, the potato was to Koch. For just as the accidental observation of the fall of an apple suggested to Newton the law of gravitation, the accidental observation of the mould upon the surface of a potato gave to Koch the clue which led to the discovery of the parasite of tuberculosis. But, as has often been observed, the accident must happen to the right person to be productive of the right result. Hundreds of men had read the work of Malthus, thousands had seen an apple fall, or had noticed, perhaps only with feelings of disgust, the decay, the rot, as it is commonly called, upon the surface of a potato, but it occurred to only these three men—posterity will put their names together—to evolve from these simple observations the greatest discoveries of modern times.

The first step in the elucidation of the cause of the acute infections, tuberculosis, and many other diseases due to micro-organisms, rested upon the substitution of a solid for a fluid culture substance; and the first solid substance used was the surface of a divided potato. Koch saw that the surface of a potato exposed to the air soon became covered with mould, which under examination by the microscope proved to be parasites and fungi of many different kinds. It occurred to him that he might secure the isolation of these different forms by grafting them individually upon fresh potatoes, and the result justified his expectations. Hereupon, he proceeded to graft the specific products of disease, and thus by successive experiments to isolate the pathogenic organisms. He soon found that all pathogenic organisms would not grow upon the potato. The parasite of milzbrand, for instance, grows luxuriantly upon the potato, but the parasite of tuberculosis does not grow upon it at all; so that to secure the isolation of these germs he was compelled to devise other solid culture substances, namely, of gelatine and of blood. But the potato was the first, and is still the best sort for certain forms of growth. To quote his own language in a publication long ago: "*Doch das Princip war gefunden und es kam nur darauf an, der Sache eine für alle Fälle passende Gestalt zu geben*" (which might read, very literally translated: Yet the principle was found, and it became merely a matter of securing a form suitable to all cases).

Up to the time of Koch, all experiments with pathogenic micro-organisms were made with culture fluids, and the impossibility of purification of the fluids used, with the implied impossibility of isolating germs of an individual kind, rendered impotent every kind of experimentation. The different, often opposite and contradictory, results arrived at by equally competent observers soon surrounded the whole subject with doubt, even ridicule, and justly brought about that state of scepticism regarding the germ theory so universally prevalent in our times.

The simple substitution of a solid for a fluid culture substance has completely changed the whole aspect of the subject, by giving at once to the study of micro-organisms a degree of scientific accuracy, which is surpassed in no other field of medicine.

I put this fact in the foreground, because, as it seems to me, it stamps the genius of the discoverer more than anything else. Given a field which is clear of weeds and it is possible to grow the grain which has been sowed. And thus it is grown here, again and again, by successive cultivations, the same seeds always producing the same fruit, if I may use so coarse a term, with the same degree of certainty as in the microscopic world. If successive observations show, without exception, the same picture under the microscope, and if successive inoculations show, without exceptions, the same results in the bodies of animals, what other inference is possible than that the micro-organisms are the cause of the disease? In the case of tuberculosis, as in that of milzbrand, septicæmia, etc., there is no question, whatever, of any chemical effects. For the bacilli and micrococci of these diseases are absolutely isolated by successive generations, sometimes to the ninetieth already, in cultured fluids, before their introduction, and they themselves, or their progeny, are universally found after the natural or artificial death of the animal in every product of the disease.

But first let us do justice to the potato. The method of its present use deserves a full description, not only because it was the first solid culture substance, but, as has been said, because for some organisms it is still the best. Moreover, the experiment can be easily made by any one, and the knowledge which the simple observation imparts will do more than words to dissipate the doubts concerning the possibility of the isolation of germs in the mind of the most incredulous.

It will be remembered that the cardinal fact to be proven is to secure the absolute isolation of individual species, and it is claimed that this isolation can be demonstrated even to the naked eye. Hence for demonstrative purposes the potato gives the most conclusive evidence. It will be readily understood that the

potato must be freed of all germs before the experiment begins, must be completely, or as nearly so as may be, sterilized at the start, and the steps by which this sterilization is reached, though tedious, perhaps, in description, will give, if patiently followed out, a good idea of the methods of work on a finer scale, as with the sterilized gelatine and blood-serum preparations.

In the first place, only such potatoes are used as are unfit for culinary purpose. A good, edible, mealy potato would break open under heat, and is hence rejected. A rather watery potato, with a sound skin, is the one selected. One of the attendants understands exactly now what kind of potato to buy. Then the outside is washed perfectly clean with a brush, a small hair-brush, under a stream of water from the hydrant. Every dark spot or surface is now scraped off with a knife, and is followed into the interior until entirely cut away. Should too many such spots occur, or should their exsection involve too much mutilation of the potato, it is cast away. The accepted potato is next scrubbed again with the brush, and is now dropped with its companions, usually to the number of six or eight, in a large glass vessel containing a solution of corrosive sublimate one part to the thousand, to which a few drops of hydrochloric acid have been added to prevent the decomposition of the fluid. Here it remains for one hour, after which it is placed immediately, that is without washing off the sublimate solution which adheres to it, in a steamer, and steamed thoroughly for half an hour. Now the potato is pretty thoroughly sterilized and is ready to officiate as a culture substance for the graft. But every thing that is to touch the potato must be sterilized in turn. First, the knives which are to cut it, one for each potato, and the glass vessels which are to receive it, one for two or three potatoes. Common shoe knives are employed, the blade of each being brought to a glow over a Bunsen's jet. The glass vessels are washed out with the sublimate solution, and covered top and bottom, that is, bowl and cover, with a large piece of moistened blotting-paper, which by reason of its moisture sticks. Now then the hands of the operator are washed with the sublimate solution. Each potato is now halved with the blade of the knife, which has meanwhile cooled down somewhat, care being taken that the hands at no time come in contact with the divided surface. Thereupon a platinum wire attached to a glass rod is also heated to redness, *ausgeglüht* is the expression, and the graft is picked up upon its point, put upon the free surface of the potato and spread over it, with a small recently *ausgeglüht* knife, just as butter is spread upon bread, or as a gardener with his rake spreads the soil over the newly sown seed. The graft is taken from a potato of former experimentation, or from a test tube containing the germ growing in a gelatine or blood culture substance, being selected from the place which shows to the naked eye the thriftiest and purest growth. The original micrococci or bacteria, independently of pathogenic organisms, are obtained by simply exposing a fresh potato to the air, when after a day or two its surface is found covered with moulds or germs of various kinds. Thus after half a dozen experiments, each potato is made to grow a special or distinct mould, without admixture with the others. Of course they soon, in their luxuriant growth, become visible to the naked eye. Moreover, some are white, some are green, some are scarlet; some look dry and mealy; some accumulate in drops, or fluidify the surface of the potato; some are arranged in rings, and so on, each showing its own peculiarity of form and color. If at any time any admixture occurs, both are seen together, and what is called a *Verunreinigung*, an impurification, has evidently taken place. The pure isolated parasite is then grafted anew upon a new potato. At any time, of course, specimens can be removed and studied under the microscope, when individual peculiarities soon come to be distinctly recognized. So potatoes are shown with a line across the free surface growing a scarlet mould upon one side of the line, and a green or white mould upon the other. Or a skilful experimenter may quarter his surface, and grow four different varieties upon it. Thus, too, are grafted upon the potato the yeast fungus, the fungus which colors milk blue in perfect purity and isolation. But the most beautiful and showy of all is the deep-scarlet *micrococcus prodigiosus*. This is the fungus which grows upon the host in damp churches and gives rise to the miracle of the sweating blood. So the merest neophyte may see at a glance whether his graft has been a success or not, and may soon satisfy himself of his ability to isolate an individual species, or to propagate it *ad infinitum*. The potatoes, though kept in the moist chamber formed by the glass vessels, soon become permeated by the parasites and fluidify in the process ordinarily called decomposition. So care must be taken to keep up a fresh supply, and these experiments are repeated every two or three days. To avoid the loss of any species, strips are cut off from time to time, dried, and preserved in bottles, whence they may be extracted at any time for new grafts. The exposure of the free surface of a sterilized potato acquaints the observer with the particular kind of germs which abound in the locality of the experiment. But the analysis of air is now made in a much more satisfactory way, and with other culture substances than the potato. The truth is, the potato is used now more for demonstrative purposes, for as soon as it was found that many pathogenic organisms would not grow well, or at all, upon the potato, search was made for other soil.

The first substitute among the *feste Nährboden* which Dr. Koch was led to employ was a mixture of gelatine with extract of beef. It would take up too much space to go over all the processes employed to secure the sterilization, the clarification, and the coagulation of the nutrient gelatine mixture, and it is especially unnecessary, inasmuch as the details have been published in Dr. Koch's first communication from the Health Office. It may suffice to say that all these objects have been obtained, and that the place bristles with tubes of gelatine and of blood, which, by the most ingenious procedures, are also brought to look like amber, and to have the consistence of gelatine when cold. These culture substances are inoculated by means of the platinum wire, some with septicæmia of various kinds, some with tuberculosis, some with milzbrand, all visible as opacities in the clear fluid, as visible as an opacity upon the cornea, or as summer clouds in a clear sky, all growing luxuriantly, and each ready at any time for examination under the microscope, or for inoculation of animals, which is practised every day. Some of these preparations are over a year old, and are, of course, just as virulent as when first introduced. Three white mice, one large rabbit, and one guinea pig were inoculated to-day, each with a different bacillus or micrococcus, and as fast as they succumb, often before natural death, each is examined for the well-known effects of the disease. Every day two or three animals are brought in and examined for tuberculosis. Some have died spontaneously of the disease when they show just the lesions we see in man; some have died quickly as the result of the injection of large quantities of tuberculous virus, *i. e.*, bacilli, when they show the lungs compressed, and atelectatic from pleuritic effusion, the result of tubercular peritonitis; some, after longer time, as the result of the injection of smaller quantities, showing the typical picture in the lungs of acute miliary tuberculosis. Mice are inoculated at the root of the tail on its dorsal surface, rabbits on the inner surface of the ear, and guinea pigs on the

side of the abdomen. In each case a small incision is made, a little skin pocket is formed by a blunt instrument, and the parasites extracted from the test-tubes with an *ausgeglühter* platinum wire, and introduced into the pocket. In experiments upon rabbits with tuberculosis, a vein of the ear is dissected down upon, incised, and penetrated with the needle of an *ausgeglühter* hypodermic syringe containing the bacilli, diluted with sterilized gelatine or water, sterilized by boiling. Every instrument used, that can be, is first heated to redness, and allowed to cool, and instruments that can not be heated to redness are put into an iron box, with a thermometer sticking out from its top, and then subjected to a sterilizing degree of heat. The culture substances, gelatine and blood, are boiled every day for a number of successive days, as long as any new opacities indicate the existence of germs or spores, before the specific bacillus or micrococcus is introduced. If at any time thereafter a microscopic examination shows the coexistence of other germs than that introduced, the specimen is thrown away as *verunreinigt*, and a new one is prepared. Here there is a laboratory filled with the quintessence of the most malignant of known diseases, any one of which can be imparted to an animal with absolute certainty, with a degree of rapidity, skill, and accuracy which would sound like a legend to the uninitiated.

So far, I have said nothing of the color tests. But this is a chapter by itself for a later date. I may say here now, however, of another part of this immense subject, that Dr. Koch does not at all believe in the practicability of the inoculation of a reduced virus in the prevention of the disease. He thinks that such experiments do more harm than good by spreading the disease, and that all that is necessary is to prevent the dissemination of the sputum which chiefly conveys the disease; for the cases of ingestion of the bacilli in meat and milk, though they do undoubtedly occur, are comparatively very rare. In the cases of bacillar meningitis which he has examined, he has always been able to find caseous bronchial or cervical glands, showing that the ingress of the bacilli was nevertheless through the lungs. Not that tuberculosis in any way implies the pre-existence of caseation. He produces it every day without caseation by injecting it directly into the blood. And even in the cases where the bacilli have been injected into the abdominal cavity, the tuberculosis of the peritoneum which followed was not preceded by any caseation of the peritoneal glands at the point of injection, or of the mesenteric glands remote from it. Caseation, when it occurs, is only an effect of tuberculosis. The only possible cause of the disease is the bacillus tuberculosis, and as this bacillus for the most part disseminates itself in the sputum, it will only be necessary to destroy the sputum to check, if not arrest, the spread of the disease.

But some one might say, Budd said this fifteen years ago. So he did; but what impression did it make? There was no proof. So the detractors of Darwin say both Goethe and Lamarck advocated the theory of descent many years before he lived. So they did; but their views were regarded as visionary until Mr. Darwin showed that the variation of species must be true, because of the struggle of numbers, and the survival of the forms best adapted to surrounding media. So the proof of the poison in the sputum is now at hand, and so soon as the knowledge of it filters down through the profession to the masses of the people, the disease will have had its day.

The promotion came to-day. In the papers it reads that *der Kaiser haben allergnädigst geruht*, etc., to promote *Regierungsrath* Dr. Robert Koch to *Geheimrath*, the grade which is just above it. J. T. W.

BERLIN, June 27, 1882.

REUNION OF DIVIDED NERVES.

To the Editor of THE MEDICAL NEWS.

SIR: In a report of the proceedings of the South Carolina State Medical Association, April 25, 1882, the President, Dr. F. L. Parker, delivered the annual address, and chose for his subject "Primary and Secondary Reunion of Divided Nerves by Suture." Dr. Parker cites cases to show that, though the operation was performed several months after injury and use of electricity, nerve power was restored.

With due respect for Dr. Parker's observations, and not in a spirit of criticism, but rather of inquiry, I would call attention to an article in THE MEDICAL NEWS of February 11, 1882, on "Nervous Degeneration, and Theory of Sir Charles Bell," by Dr. Dalton, in regard to change of structure of a nerve, after it has been divided. In relation to this subject there are two points worthy of investigation.

1. Is Sir Charles Bell's theory the true mode of repair of divided nerve?

2. In suture of divided ends of nerves, do the ends unite, as it were, by first intention, and restore function, or is it probable that, though the nerve may unite by suture, the function is restored only by cicatricial tissue and degeneration and regeneration of nerve below the point of section?

Allow me to narrate a case in point. Harry E., aged thirty-five, blacksmith, while working in shop on October 26, 1880, accidentally received the point of a heated iron rod in the popliteal region, a few inches from insertion of biceps, severing the external popliteal nerve—so inferred from location of wound and results following, as paralysis of muscles supplied by the distribution of this nerve, and loss of both sensation and motion.

In consultation with other physicians, little encouragement was given as to the limb being as useful as before the accident. In walking, the patient had to keep the foot flexed with a strap for several months after injury. In May, 1881, sensation and motion was noticed in the paralyzed muscles, and since then improvement has steadily taken place, the patient being now almost fully recovered.

To give an idea of the degree of paralysis, particularly of sensation, I will state that, in December, 1880, a few months after injury, the patient, while reading, without knowing, held the great toe of the injured limb to a red-hot stove until severely burned, without any manifestation of pain.

Since treating this case, I have read the article by Dr. Dalton on Bell's theory. That is, when a nerve is divided, either motor or sensor, the function was lost, but not permanently, as the ends of the nerve reunite by cicatricial tissue, in which are found new connecting fibres of new formation. The degeneration of the divided nerve is below the point of section, and extends through its whole ramifications; and when the nerve function is restored, it is by a true process of regeneration, that is, the growth of new fibres throughout the separated portion of the nerve.

From the fact that there was no treatment other than that directed to the healing of the wound in the preceding case, its history favors Bell's theory as being the correct one, and I incline to think it is the true mode of repair.

THAD. DONOHUE, M.D.

MEMPHIS, TENN., July 5, 1882.

WHO FIRST OBSERVED DESQUAMATION OF VASCULAR ENDOTHELIUM?

To the Editor of THE MEDICAL NEWS.

DEAR SIR: My attention was lately drawn to a letter in your issue for June 17, 1882, which struck me as a

curious medley of self-contradictions, misstatements of fact, and leaps at conclusions.

In one of a course of ten lectures upon the *Histology of Inflammation*, published in abstract in THE NEWS, May 20, 1882, while speaking of the normal histology of the bloodvessels, I particularly directed attention to one of the physiological functions, which more than five years ago I claimed for the endothelial cells which line the inner surface of the bloodvessels, viz., that of *desquamation* and the *formation of white blood-corpuscles.*

These views and the observations upon which they were based were first *expressed* in a Warren Triennial Prize Essay, January, 1877. They were first publicly advanced June, 1878, in a lecture on *Reparatory Inflammation in Arteries after Ligature, Acupressure, and Torsion*, delivered at Washington. They were first *printed* in April, 1879, in *Smithsonian Miscellaneous Collections, No. 321.* They were again printed in the American translation of Cornil and Ranvier's *Pathological Histology*, January, 1880.

Dr. Wendt, the writer of the letter referred to, says that he announced similar "views as originating from personal observations," in July, 1880, which were again somewhat amplified in Satterthwaite's *Manual of Normal Histology*, 1881. He contradicts this statement, however, in another paragraph, using the words "I never claimed that I actually observed any such process" (*i. e.*, desquamation of vesicular endothelial cells). In the last paragraph of his letter he does not hesitate to admit the rather *theoretical* nature of the reasoning upon which is based his belief in an endothelial desquamation within the bloodvessels.

An examination of his papers, as above cited, shows that Dr. Wendt very dogmatically asserted a normal desquamation of the vascular endothelium, and making a bold leap from that pure assumption, landed upon the conclusion that broken degenerated pieces of a desquamated endothelial cell give rise to the corpuscles of the blood—an assumption which was admitted (*loc. cit.*) to be "insufficiently substantiated by known facts," yet which to his mind appeared to need no basis other than an observed desquamation of the endothelium from the serous surface of a frog's mesentery under the stimulus of inflammatory irritation.

In the letter above mentioned Dr. Wendt states that he has very carefully studied the reports of my observations, during which I saw in the field of the microscope the endothelium actually *desquamate* from the walls of capillary *bloodvessels* in the mesentery of a living frog, and says, with the most surprising complacency, that he deems such pertinent observations "wholly superfluous," preferring to base his assumptions "insufficiently substantiated by facts" upon the supposed analogy between the peritoneal endothelium and that which lines the lumen of the bloodvessels. Such self-complacency appears to be equalled only by the extraordinry *sangfroid* with which he still claims priority for an original observation.

The author of the letter again places himself in conflict with the facts (wilfully, it appears, since he claims to have carefully studied my papers) when he avers in the last paragraph that I never intimated the possibility of the origin of white elements of the blood as due to a physiological desquamation of the lining endothelia of the vessels.

In the already cited lecture, delivered June, 1878, upon page 57, any one interested in learning the truth will find among the conclusions deduced, the following:

"21st. The endothelium which lines the inner surface of the arteries and capillaries may be considered the source of origin of some of the increased number of colorless elements of the blood in local inflammations. From this conclusion naturally issues the corollary that the endothelia in general may be considered as some of the possible physiological progenitors of the colorless elements of the blood. See Fig. 11."

Identical views were advanced more than five years ago in the prize essay already mentioned, and were last published in the translation of Cornil and Ranvier's *Pathology* also already referred to, the latter, seven months before Dr. Wendt's first paper. This last work, as I learn, is used as a text-book in the medical schools of the city in which Dr. Wendt resides.

Whether or not "Dr. Shakespeare's claim to priority lacks the substantiation of facts," I leave to those of your readers who are in search of truth.

Promising not to trouble you again upon this subject, I am, sir, Yours, very truly,

E. O. SHAKESPEARE.

NEWS ITEMS.

KANSAS CITY.

(From our Special Correspondent.)

PURPURA HÆMORRHAGICA.—At the May meeting of the Jackson County Medical Society, Dr. Charles W. Adams presented a marked case of morbus maculosus, or the spotted disease of Werlhof, with a family history which would seem to establish clearly a hemorrhagic diathesis. The case presented was that of a schoolgirl, aged twelve years, and of American parentage. The inherited predisposition to hemorrhage is seen by tracing the family history. The girl's only brother, a strumous lad, suffers frequently with copious hemorrhages from the superficial and deep mucous membranes of the body, particularly from the nose. The mother, who menstruated freely at the age of eleven, has for years suffered with periodic hemorrhages from the bowel, and with internal hæmorrhoids. The father is one of those full-blooded, plethoric individuals, with a ruddy face, in which the capillary network of vessels are distinctly visible, and in whom slight cuts bleed with more than ordinary freedom. This varicose condition of the smaller vessels is not limited to the father, but is common to the whole family from the grandfather down, affecting to a greater or less extent the face and all the extremities. This tendency is particularly well marked in the mother.

The girl herself has never before suffered from bleeding, nor has she menstruated. The present attack began with mild prodromal symptoms of an undicided character. On April 3, 1882, the patient suffered with pain in the joints, particularly those of the lower extremities—the knees and ankles. The feet and ankles were very much swollen, and the overlying integument was covered with a bright red petechial exanthem. These spots of extravasated blood varied in size from a pin's head to that of a dime-piece. Besides these smaller petechiæ, there were occasional spots of dark brown discoloration (resembling the old-fashioned "liver marks," being of irregular form, and varying in size from one-half to two inches in diameter) upon different portions of the body. Temperature, 99.5° Fahr.

April 4.—No new petechiæ or blood spots; less swelling in feet and ankles; general condition improved; temperature 99° Fahr.; pulse moderately full and regular, 88.

5th.—Morning: Petechial eruption appeared on right hand and forearm; stomach very irritable, vomits frequently, can retain nothing; bowels very loose, passing large quantities of greenish mucus, with blood; temperature 99.6° Fahr.; pulse 94. Evening: Petechiæ appearing on the right arm, shoulder, and extending on down the back, with especially large ecchymoses about

the shoulder-blades; old petechiæ on foot and ankle changing to brownish discolorations, and disappearing; bloody stools; temperature 99.3° Fahr.; pulse 80.

6th.—Patient passed a restlsss night; temperature 100° Fahr.; pulse moderately full, 90; tongue dry and coated; no vomiting, and no pain in joints; old petechiæ fading on hand and arm; new purplish-red spots about the bridge of the nose and the forehead.

7th.—Temperature 99.5° Fahr.; pulse 95; passed a comfortable night and had a free movement of bowels.

In the morning a few petechiæ appeared on the chin, and by noon the whole chin, lower lip, anterior portion of the neck, and a large part of both cheeks were purplish-black, with irregular-shaped ecchymoses. The parts were painful, and also very much swollen, so much so that the countenance was scarcely recognizable. There were weakness and prostration, and for the next thirty-six hours the patient remained in this critical condition, without material change, except a slight rise in temperature.

9th.—Temperature 101° Fahr.; pulse feeble, 110. There were fresh petechiæ on arms and shoulders, and a slight extension of the eruption on the face. The ecchymosed tissues about the lower part of the face were very badly swollen. A large portion of the lower lip, including considerable of its mucous membrane and its integumentary covering, together with a large share of the underlying tissues, sloughed *en masse*, giving marked disfigurement. During the next forty-eight hours there was an amelioration of all the symptoms.

11th.—Considerable improvement in general health, appetite returning, and fever abated. Old petechiæ on hand, arm, and back disappeared.

12th.—An injection was given to relieve the bowel. After this was done, petechiæ reappeared on the hands and arms. Again, on the 15th, after an injection, petechiæ almost immediately reappeared upon the feet and ankles. This tendency of blood-spots to reappear after a passage from the bowel was for some time observed after each free movement. The case made a moderately rapid convalescence, with the exception of the lower lip, which was slow in healing, and upon which skin-grafting was practised.

In regard to the treatment, reliance was placed upon the oil of turpentine, it being given in ten-drop doses, in emulsion, every three hours during the greater part of the illness. The mineral acids and the juice of the lemon and lime were resorted to early in the treatment of the case, but were invariably rejected by the stomach. Quinia and alcoholic stimulants were also given with regularity during the treatment. A wash, composed of tannic acid and brandy (℥j to f℥viij), was used locally and thought to have a good effect in the way of constringing the capillaries and allaying troublesome itching.

Remarks.—This case illustrates very well one of the exceptions to the ordinary rule that purpura hæmorrhagica largely occurs in weak and anæmic subjects, and shows that the naturally strong and plethoric have no immunity from the disease. It also points to the fact that hereditary predisposition often has much to do with its development. And, moreover, it would seem to contradict the assertion of those who hold that purpura hæmorrhagica does not invade the integument of the face.

VIENNA.

(*From our Special Correspondent.*)

Honor to Prof. v. Arlt.—Prof. Arlt has recently received the "Comthur" (Commander) Cross of St. Michael's Order of Merit.

Langenbeck's Successor.—It is announced in Berlin that the Faculty of Medicine have proposed to the Ministerium the name of Prof. Richard Volkmann, of Halle, as successor to Langenbeck. Richard Volkmann was born in Leipsic, 1830, is a son of the formerly famous physiologist and anatomist, Volkmann, who was transferred from Dorpat to Halle, and who died in 1878. Prof. Richard Volkmann received his first surgical training under the eyes of Blasius, the renowned surgeon of Halle, and later became the pupil of Langenbeck. Still later, he was appointed Docent of Surgery in Halle, where, as the first assistant of Blasius, who was suffering at the time from an affection of the eyes which incapacitated him for the performance of most operative procedures, he perfected his many-sided surgical education. Germany is indebted to Volkmann, more than to any other individual, for the introduction into surgical practices of Listerian principles.

Medical Notes from Italy. *Ovariotomies.*—Dr. Fernando Franzolini performed two operations on June 1st at the Civil Hospital of Udine—one on a girl of 19, with an unilocular cyst, duration 28 minutes, and the other on a woman of 53, having a large cystoma of the left ovary, with extensive peritoneal adhesions; duration an hour and ten minutes. No drainage employed; Lister method; cases promised well at time of report. These were the seventeenth and eighteenth ovariotomies of Dr. Franzolini. [He was the first in Italy to safely remove the entire uterus and ovaries, and has also extirpated a hypertrophied spleen with entire success; his only Porro operation was fatal, as the woman was in extremis from a pulmonary complication.—Ed.]

Total Extirpation of Uterus per Vaginam.—Dr. Calderini operated on May 14th at the Obstetric Institute of Parma, in a case of uterine sarcoma. The woman died of exhaustion in four days. The last operation by Dr. Margary, at the St. Giovanni Hospital of Turin, resulted favorably.

Appointments and Changes.—Dr. Paolo Negri, Second Assistant of the Obstetrical School of Milan, has been appointed, through the *concours*, to the post of Professor and Director of the School of Obstetrics in Novara. Prof. Chiara, chief of the same school in Milan, under a proposition of the Faculty of Florence, with the approval of the Superior Council of Public Instruction, has been appointed ordinary Professor of Obstetrics and Gynecology in the "Instituto di perfezionamento" of Florence. Dr. Luigi Mangiagalli, First Assistant of the same school in Milan, has been elected extraordinary Professor of Obstetrics and Director of Clinical Obstetrics in the Royal University of Sassari. Prof. Edoardo Porro, of Cæsarian fame, has been appointed to succeed Prof. Chiara, as Chief of the Royal Obstetrical School of Milan.—*L'Independente di Torino*, 5 Giugno, 1882.

Drs. Porro, Chiara, Mangiagalli, and Negri, thus honored, have together performed *Cæsarian Ovarohysterectomy* nine times, and saved seven women and nine children. Dr. Porro, in his new position, will have greatly increased opportunities for testing the value of his operation. Who are to be his two aids has not yet been announced. Dr. Nicolini was his assistant at Pavia, and saved a woman and child in a private Porro operation. The school in Milan will have an entirely new faculty.

Health in Michigan.—Reports to the State Board of Health, for the week ending July 15, 1882, indicate that cholera infantum has considerably increased; cholera morbus, consumption of lungs, intermittent fever and dyentery have increased, and that neuralgia, remittent fever and diarrhœa have decreased in area of prevalence.

Including reports by regular observers and by others, small-pox was reported present during the week ending July 15, and since, at 5 places, as follows: at Detroit (4 cases), at Flint (20 cases), at Lansing (one case), July 15; at Grand Rapids (3 new cases), July 16, and in the township of Greenfield, Wayne Co., July 19.

SANITARY EXHIBITION OF THE NEW JERSEY STATE BOARD OF HEALTH.—An exhibition of sanitary, household, and ornamental articles and appliances will be held at Waverly, N. J., commencing Sept. 18 and lasting one week, under the auspices of the New Jersey State Board of Health.

CONGRESS MEMORIALIZED TO CONTINUE THE POWERS OF THE NATIONAL BOARD OF HEALTH.—The State Board of Health of Michigan has forwarded the following memorial to Congress:

Your memorialists, the Michigan State Board of Health, respectfully represent:

That small-pox, diphtheria, and scarlet fever, have been and are being repeatedly introduced into this State by immigrants newly arrived from foreign infected places, and by travellers who have come in contact with such immigrants; that because of the rapidity of travel, and the vast amount of inter-State travel, it is impossible for State or local boards of health, without extraordinary interference with inter-State commerce, to successfully quarantine against or effectually control these diseases while the United States Government permits one or more of them to be introduced so frequently as of late by immigrant vessels which reach this country; that while in ordinary years the introduction of scarlet fever and diphtheria is believed to be of exceeding consequence in causing epidemics, in swelling the death-rates, sickness-rates, pauperism, and general suffering, cholera and yellow fever are sometimes thus introduced, and at the present time small-pox is causing especially wide-spread disaster in this and other Western States; that, by reason of such introduction of diseases, the lives, health, and happiness—those dearest and most important interests of our people—are constantly destroyed or placed in imminent danger from those foreign pestilences from which it is entirely possible for the United States Government to afford protection; that we believe that it is the highest duty of a government to protect the lives of its citizens from dangers which threaten all, and from which no other than governmental protection is adequate; that it is with deepest apprehension that this State Board of Health learns that by reason of insufficient provisions, in the Sundry Civil Service Appropriation Bill, for the National Board of Health, the important work which that Board has lately commenced and is expected to do is likely to be crippled; that this Board believes that now, more than ever before, is a most inopportune time to lessen in any way the activity and usefulness of the National Board of Health, believing as this Board does, that there is no other governmental department, bureau, or "service" so closely connected with the highest interests of all citizens and of humanity.

Therefore this State Board of Health earnestly prays Congress to grant sufficient appropriations to the National Board of Health, and to make such other provisions as will enable it to continue the immigrant-inspection service at all important ports of entry, and on important lines of travel, and to provide in every possible way for the protection of the whole country from cholera and yellow fever, and also from those contagious diseases hereinbefore mentioned which are well known as causing the most deaths and distress, throughout the greater portion of this country.

By direction and on behalf of the Michigan State Board of Health.

NOTES AND QUERIES.

MALIGNANT MALARIAL FEVER.

To the Editor of THE MEDICAL NEWS.

Sir: There exists along the rivers and water-courses in the mountains of Northern Arkansas, a disease characterized by incessant nausea and vomiting, obstinate constipation of bowels, pulse large, slow, and compressible in most cases, in extreme cases quick and wiry. Respiration sighing; temperature, as a rule, low, seldom exceeding 102° Fahr.; much jactitation; tongue broad, indented at the borders, and covered with a moist, white glazed coat; pupils somewhat dilated, and reacting sluggishly to light; skin usually moist, and in mild cases the face is flushed, in the more severe sallow or sodden. The disease occurs in the latter part of summer and early autumn. The laity attribute it to the milk and flesh of cows (milk sickness). Many physicians regard it as a malignant form of malarial fever. I have never seen anything like it in the swamps of the South during four years' experience there. It is useless to say the disease is often fatal. The usual treatment here is alcoholic stimulation, quinia, and laxative enemata.

Any information obtained as to its etiology, nature, or treatment will be thankfully received, for not having access to any extensive library, I have no means of knowing anything of its literature or obtaining any knowledge in regard to it except by observation.

Respectfully,

J. T. CLEGG.

SILOAM SPRINGS, ARK., July 13, 1882.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT, U. S. ARMY, FROM JULY 17 TO JULY 24, 1882.

CORSON, J. K., *Captain and Assistant Surgeon.*—Relieved from duty in Department of Arizona, to proceed to Philadelphia, Pa., and on arrival, report by letter to the Surgeon General.—*S. O. 164, A. G. O., July 17, 1882.*

ELBREY, F. W., *Captain and Assistant Surgeon.*—Granted leave of absence for six months on surgeon's certificate of disability.—*S. O. 168, A. G. O., July 21, 1882.*

HOPKINS, WILLIAM E., *First Lieutenant and Assistant Surgeon* (recently appointed).—To report by letter to the Commanding General, Department of the East, for assignment to temporary duty.—*S. O. 164, c. s., A. G. O.*

BARROWS, CHARLES C., *First Lieutenant and Assistant Surgeon* (recently appointed).—To report in person to the Commanding General, Department of Arizona, for assignment to duty.—*S. O. 164, c. s., A. G. O.*

MUNDAY, BENJAMIN, *First Lieutenant and Assistant Surgeon* (recently appointed).—Assigned to temporary duty at Willet's Point, N. Y.—*S. O., 164, c. s., A. G. O.*

WILSON, GEORGE F., *First Lieutenant and Assistant Surgeon* (recently appointed).—To report in person to the Commanding General, Department of the Columbia, for assignment to duty.—*S. O. 164, c. s., A. G. O.*

OWEN, JR., WILLIAM O., *First Lieutenant and Assistant Surgeon* (recently appointed).—To report in person to the Commanding General, Department of the Columbia, for assignment to duty.—*S. O. 164, c. s., A. G. O.*

EGAN, PETER R., *First Lieutenant and Assistant Surgeon* (recently appointed).—Assigned to temporary duty at the recruiting depot, David's Island, N. Y.—*S. O. 164, c. s., A. G. O.*

WAKEMAN, WILLIAM J., *First Lieutenant and Assistant Surgeon* (recently appointed).—Assigned to temporary duty at Columbus Barracks, Ohio.—*S. O. 164, c. s., A. G. O.*

EVARTS, EDWARD, *First Lieutenant and Assistant Surgeon* (recently appointed).—To report in person to the Commanding General, Department of the Columbia, October 1, 1882, for assignment to duty.—*S. O. 164, c. s., A. G. O.*

CARVALLO, CARLOS, *Captain and Assistant Surgeon.*—Died at Boston, Mass., on July 23, 1882.

THE MEDICAL NEWS *will be pleased to receive early intelligence of local events of general medical interest, or which it is desirable to bring to the notice of the profession.*

Local papers containing reports or news items should be marked.

Letters, whether written for publication or private information, must be authenticated by the names and addresses of their writers—of course not necessarily for publication.

All communications relating to the editorial department of the NEWS *should be addressed to No. 1004 Walnut Street, Philadelphia.*

ORIGINAL LECTURES.

THE PATHOLOGY OF PUERPERAL ECLAMPSIA.

Abstract of a Clinical Lecture delivered at the Vienna General Hospital.

BY PROF. JOSEPH SPAETH.

(*Specially reported for* THE MEDICAL NEWS.)

THE subject constituting the text of the following remarks was a powerfully built, well-nourished peasant woman, who was delivered at two o'clock A.M., and who was attacked one-quarter of an hour after delivery with an eclamptic seizure. The seizure lasted but a short time, and did not repeat itself during the course of the day. At the time of presentation before the class, the patient had apparently recovered, and was perfectly conscious. The temperature was not elevated directly after the seizure, and showed no important deviation from the normal during the following day. No albumen was demonstrable in the urine.

If, said Prof. Spæth, we inquire into the etiology of this particular seizure, we will find that the causes are no more detectable than those of puerperal eclampsia in general. About the whole subject we know nothing positively. Up to the year 1843, very indefinite conceptions of the causes of this affection were expressed in such vague, general terms as 'nervousness,' 'disposition to convulsions,' 'reflex excitability,' *et id genus omne*. When we observe that eclamptic seizures occur just as frequently among the heartiest peasant women as among the most delicate females in a large city, we must give up the condition of the necessary antecedency of a feeble constitution. A so-called transposition or metastasis of pains was then accepted as the cause of the seizures, and this was bound up with the obscure idea that the innervation which normally should have effected uterine contractions, was exercised upon the muscular structures of the trunk. In 1843, a substantial advance was made in this inquiry. It was asserted that albuminuria could be demonstrated in every case of eclampsia, and that the convulsions were initiated by the altered condition of the blood resulting from morbus Brightii. Frerichs declared the symptoms to be uræmic, and originated the theory that the products of decomposition of the urine, in particular, carbonate of ammonium, acted as irritants upon the nerve-centres. Frerichs further asserted, in proof of his position, that carbonate of ammonium could be detected in the expired air of a patient suffering from eclampsia parturientium, by holding up before the mouth and nose of the individual a glass rod moistened with hydrochloric acid, whereupon a thick, white cloud of ammonium chloride would be deposited. When, however, in actual fact, this experiment does succeed, which is by no means always, it must be borne in mind, that ammonium carbonate can arise just as easily from putrefactive changes in the air of the sick-room, as from metamorphoses within the body of the patient. Frerichs recommended, as the resultant of his theory, the administration of benzoic acid in puerperal eclampsia.

Other cases of eclampsia, however, were observed where no morbus Brightii was demonstrable, and where no disease of the kidneys whatsoever could be determined. Rosenstein then set up the theory that serous exudation into the brain was the cause of eclampsia. He affirmed that œdema of the cortex cerebri induced coma, while œdema of the more deeply lying convolutions produced convulsions. Pregnant women, as a fact, have a significant disposition towards œdema, and this is to be explained by the fact that the blood of pregnant women is relatively poor in albumen. Every elevation of arterial blood-pressure aids transudation of serum. Now, we know that activity of the muscles causes a rise in blood-pressure, and it is plainly to be seen that during delivery, when the labor pains call into functional activity every muscle in the body, a very significant elevation of arterial blood-pressure must ensue. Rosenstein's theory must seem very plausible, but, on the other hand, Spiegelberg, about ten years ago, injected into the veins of dogs ammonium carbonate, and caused thereby convulsions.

Statistical collections of observed cases of eclampsia give a large number where no albumen was demonstrable in the urine, and where the autopsy revealed no disease whatsoever of the kidneys. After this *résumé*, we must conclude that neither the theory of Frerichs, nor of Rosenstein, is extensive enough to cover all cases, and that, as regards the etiology of the affection, we know nothing positively.

One interesting feature about eclampsia is that isolated, single cases extremely seldom occur; when one case is observed, we can always rest assured that a number will immediately follow. The case before us can be characterized as an extremely light attack, as there has been but one seizure, and the patient is already conscious. In genuine eclampsia, the seizures repeat themselves in great, sometimes fabulous, numbers, as many as sixty and over. The intervals are of very various duration; they may last minutes, or even days.

Kiwisch has affirmed that eclampsia only occurs in women in labor. Cases are not rare, however, in which eclampsia has occurred during pregnancy; evacuation of the uterus, in these cases, soon follows, however. In the first half of pregnancy eclampsia is never observed.

The treatment must be directed by the view we take of the etiology and pathology of the affection. Formerly, derivatives and rubefacients were employed largely. Revulsion, by means of the rectum, was formerly also a very popular remedy. Among alteratives, tartar emetic was extensively used, usually one grain tartar emetic to six ounces decoctum altheæ, in tablespoonful doses, was exhibited during the course of the day. In the unconscious condition of the patient, the folly of the administration of this drug is sufficiently obvious.

Later, when the essence of the disease was supposed to be a congestion of the spinal cord, blood-letting was extensively advocated. By all rational practitioners of medicine, this method of treatment has been abandoned, since it has been abundantly demonstrated by post-mortem examinations that eclamptic patients die of œdema of the lungs, and that the brain and spinal cord is in an anæmie condition.

The most generally accepted treatment, at present, is the use of all forms of narcotics. Probably the best results are obtained by the conjoint employment of chloroform inhalations and subcutaneous injections of morphia. This treatment was accepted by Rosenstein as quieting the muscular system and thereby preventing a rise in arterial blood-pressure.

ORIGINAL ARTICLES.

THE COMPARATIVE VALUE OF LARGE AND SMALL DOSES, AND LONG AND SHORT INTERVALS, IN THE ADMINISTRATION OF MEDICINES.

BY J. R. BLACK, M.D.,
OF NEWARK, OHIO.

I am unable to perceive any good grounds for the routine plan of ordering medicines to be taken every two, three, or four hours, except that in some instances their more ostensible or gross effects begin to pass off at about these intervals. If the inquiry be made of the ordinary practitioner why he orders the administration of his doses at such intervals, he would be puzzled to give any other answer than that cited, or perhaps refers to authority for it only; and, so far as authorities are concerned, they seldom assign any reasons other than the above for such arbitrary rules, and in a purely incidental way. In fact, the more any one thinks about the method, the more does it appear in the main as a crystallized habit or a simple following of established routine handed down from one generation to another. But even the well-grounded observation that the maximum effects of some medicines begin to subside at such approximate intervals furnishes no adequate reasons for concluding that like rules appertain to all, or even to the larger number of medicines, nor even for the supposition that the maxima of effects are the most efficient for the removal of disease. The appearance and disappearance of the extreme effect of a diaphoretic or of a diuretic may be much more brief or more extended than the three-hour interval; so may that of an opiate, or of a dose of quinia.

But granting that the maxima of gross effects of medicines appear at about these intervals, and that a repetition of them is required for their maintenance, by no means proves that large and distantly repeated dosing is the most conducive to steady therapeutical results, or that it is the best in most instances for the removal of disease. Assuming gastric imbibition to be in a nearly normal state, and remembering the fact that the blood makes its circuit in about every three minutes, and assuming it to be the object to act upon the blood or upon the nervous system, or upon some functional derangement of an organ more or less remote from the stomach; and, above all, assuming it to be the object to render the influence of a medicine, as far as practicable, as uniform and continuous as that of the disease, so as to oppose, modify, or subdue it, then we equally fail to discern the wisdom of ordering large and distantly repeated dosing.

Besides, the practical applications of several large and important classes of remedies show no maxima and minima effects on which to base a rational pretext for prescribing large and distantly repeated potions. Such is true of alteratives, of febrifuges, and of tonics. Their immediate and mediate effects, it is commonly impossible clearly to discern, while the rule of dosage is usually all that the stomach can well bear. Perhaps the rule of three- or four-hour intervals first arose during the crude conceptions of times long gone by, when medicines, like food, were supposed to need a certain period for proper assimilation; and hence, as large potions of them as the stomach and system could well tolerate were ordered, and to be taken at about meal intervals. The object of this paper is to inquire if such a method is the best, not only for rendering the most effectual assistance to the *vis medicatrix naturæ*, in the removal of disease, but also for promoting and popularizing the practical applications of the healing art, by rendering our prescriptions much less offensive and distressing than they now are.

Disease, with comparatively few exceptions, is a continued state of abnormal action for more or less extended periods, though subject commonly to one or two diurnal exacerbations. Examined more closely, and with instruments of precision, its phenomena in general terms are found to involve molecular changes of peculiar kinds, whose energy usually far exceed those which pertain to the healthy state. That unusually swift transformations and disintegrations of the blood and tissues are going on in states of disease, is amply confirmed, deductively, by the abnormally high temperature, the rapidity of the circulation, the general restlessness, the insomnia, and the copious ejections of retrograde organic matters from the system through its various outlets. The high temperature alone warrants the conclusion that a swifter rate of transformation is in progress than ordinary.

Turning now from these generalities in reference to acute diseases to those of a chronic type, we find that although there is not the same evidence of a like rapid metamorphosis of a systemic kind, an intimate knowledge of the morbid state nearly always renders it apparent that at the chief point or points of abnormality the same, though a more limited, sphere of unnatural metamorphic change is in progress. This may be pronounced to be invariable, except in the sequelæ of an aborted organic metamorphosis, as, for instance, the benign sclerosis of some important tissue. But it is here specially worthy of remembrance that during the inception and maturation of a morbid process, confined to some organ or special tissue of the body, the rule of undue molecular change and the enhancement of morbid energy are not subject to any *omni bihori* or *quad nihoro* rule.

Pathological action being then very much the same as the physiological in continuity, we are again led to inquire on what grounds are medicines ordered to be taken at two, three, or four-hour intervals, and usually in doses as large as the stomach can bear, or to the utmost limit of safety upon the functional integrity of some organ of the body. Is the organism better enabled to throw off disease by disturbing medication, or by heavy strokes, so to speak, repeated at three- or four-hour intervals, or by the proper recognizance of the principle, that as morbid processes are usually only subject to minor variations in the continuity of their energy, our counteracting agencies should be subject to like rules? If the latter, then it follows as a necessary corollary that remedies should be administered in

much smaller doses than they now are, and at far shorter intervals. This is the point which I wish the reader to consider with me.

It has been abundantly proven that liquid or soluble medicines usually make their appearance in perceptible quantities in the urine or other excretions or secretions, in from five to thirty minutes after administration; much, of course, depending upon the energy of absorption, and the functional state of the secreting or excreting organs. These may be inordinately active or inactive—points which do not here concern us—the rule being within the limits given.

Suppose, then, it to be the object, which no one will deny, of the therapist to modify beneficially the molecular energy of disease, by the molecular energy of a medicinal substance, is it not the most rational mode not to distress or embarrass the stomach by heroic doses of it, but to order small ones often repeated? Such a course commends itself to the judgment on several considerations, some of which I shall here adduce. The administration of medicine in full doses is very apt to beget some gastric distress bordering upon, or actually productive of, nausea, with or without vomiting. The mere fact that such a condition has ensued is, *per se*, evidence that the stomach has set up actions (reversed vermicular movements) to expel the medicament, and this being the state the least of all favorable to prompt imbibition, the hindrance of therapeutical effect is thus successfully accomplished. The spontaneous occurrence in health of nausea after eating or drinking denotes the arrest of gastric assimilation, and is it not plain that its induced state must also be productive of a like arrest for longer or shorter periods? Of course, when vomiting or temporary nausea is the object desired, the larger dose is justified, but when it is the purpose to have a medicine affect the system at large, and act upon or through the blood, the unsuitableness of large doses for a prompt and steady effect is sufficiently evident. Besides the retarded effects of large doses of medicine, they not unfrequently injure the stomach, giving rise to uneasiness bordering on pain, the nausea frequently reaching the grade of emesis; or else by increased downward peristalsis, the medicine is passed quickly into the intestines, where it is either expelled in larger part, or rendered almost nugatory by diminished regional absorption, and by admixture with the fecal contents.

In nearly all forms of disease, the object of the therapist being to modify morbid energy, and usually more in one special organ or tissue than others, a little reflection ought to make it, to say the least, more than probable that this can better be accomplished by small and oft-repeated doses than by the opposite method. The imbibition of a medicine is not a spasmodic but a continuous process, nor does the medicament require two or three hours for digestive assimilation. Whenever a steady impression or a continuous morbid process is desirable (and when is it not?), the frequent administration of the medical agent has the best apparent correspondence to the internal process. A nicer adjustment of therapeutical energy to vital actions is not only thus attained, but flood-tides of distressing or alarming effects from the over-effects of medicines are obviated, as are also the cumulative perturbations of function, now excessive, then defective, or may be perverted. Indeed, the disturbances of function from large doses are often so profound, that the over-effect of one medicine needs to be corrected by another, thus compelling the medical attendant to turn his attention to the correction of his own errors, instead of fixing it upon the disease he is attempting to manage.

Not a few physicians seem to take a sort of coarse-minded delight in producing startling effects by their prescriptions. If a patient be made very much more sick by the medicine than he was by the disease, if he has been vomited or purged severely, and not much the worse for it, such a pill-dispenser is disposed to regard the strength of his potions with a pleased serenity. But it may be—indeed, frequently is—the case that he is put upon the defensive to justify such a severe course as a therapeutical necessity; and he also often perceives the necessity of correcting the extreme effects of his doses. All I have to say to such is a repetition of the golden rule—do not to others which you would not wish done to yourself. One thorough personal experience of that kind every such physician should be made to undergo. I am far from asserting that heroic doses, or even distressing effects from the action of medicines, are never justifiable, but only this, that, as a rule, by small and frequent repetitions of them better therapeutical effects are almost invariably obtained, and in a manner scarcely disagreeable; more refined, prompt, and decisive, because more congruous with the unbroken and ceaseless play of the functions in the most delicate and nicely adjusted organism with which man has to deal.

But over all evidential statements in favor of this reformation rises that of experimental observation. Let the doubting reader give the plan here advocated a fair trial in any appropriate cases of disease, and, if a good observer, apt to discern something more than the production of crass effects —which any boor can—viz., the far more subtle indications of improvement in the action and interaction of the vital functions, then I doubt not of agreement. Or suppose it to be desirable to increase a secretion or excretion; suppose it to be desirable to bring the energy of a medicine to bear upon a special organ or tissue, so as to modify its functions for the better; suppose it to be desirable to produce an alterative effect upon the organism as a whole, let small and oft-repeated doses be ordered, and the adduction of further argument on superiority would not be required. Suppose aconite is deemed to be the appropriate remedy, say for a facial neuralgia, let drop doses of the fluid extract of the root be prescribed, every half hour or hour, according to the urgency of the pain, and when this begins to abate, lessen the dose or extend the interval, until complete relief is afforded. Or suppose that free biliary and intestinal excretion presents itself as the indication to be carried out, let half-grain granules

of calomel be alternated every hour with granules of aloin of the same size, and a free, easy, and steady outflow will be produced, the calomel exciting (despite Bennett's experiments) the discharge of bile from the liver, and the aloin, by its influence upon the large intestine, insuring its expulsion from the body. All this can usually be carried out without producing the sickness, nausea, and malaise which ordinarily follow the administration of enough of these agents, at a single dose, for the production of a like effect. Or suppose that Fowler's solution contains the kind of energy needed for the removal of disease, let a drop be ordered every hour or half hour, and the therapeutical effects will be superior to doses as large as the stomach can well bear taken two or three times a day. The reasons why, are not difficult to apprehend. The ten-minim dose, if taken on an empty stomach, not unfrequently acts as an irritant, and thus defeats partially or entirely the purpose of its administration, while, if taken after meals, its action is somewhat delayed, and its influence in part lost by admixture with excrementitious matters. But if taken in much smaller doses, and at shorter intervals, an immediate irritant effect is obviated, and, by the law of averages, a more certain and uniform mean of effects is obtained during the variable states of the stomach and its contents.

Or, again, small and often repeated doses are peculiarly appropriate in cases of gastric debility, irritability, and in diarrhœal and dysenteric disorders. What are known as full doses of almost any medicine, nay, even of foods and drinks, often defeat the purposes for which they are taken by acting as repelling irritants on the gastric and intestinal villi, whereas small and frequently repeated ones do not arouse and excite vital resistance like a large and rough bolus. In almost all forms of disease the sensibility of the stomach, like that of the nerves at large, is usually in an exalted condition, with its functional activity more or less in a state of abeyance, and yet the rule in prescribing is to make the dose as large as the stomach can well tolerate. Either unintended extreme or irregular effects are thus almost sure to arise, results it has long been the universal habit of physicians to guard against only, instead of seeking radically to abolish. By rendering the applications of medical energy more nearly synchronous with that of a morbid process, not only would these untoward effects be obviated, but the energy of quickly successive administrations would be more equably diffused, more continuous, and more in harmony with that of the disease which it is the object to modify.

It may occur as an objection to the method of administration here advocated that the eliminative organs may carry small portions of a medicine out of the system before it evolves the characteristic effect of a large dose, and so cause a failure of the object intended. In other words, if a saline be prescribed to act as a purgative, if the dose is small and frequently repeated, the effect may be simply that of diuresis. That such is the operation of some salines when only a few small doses are ordered, the most ordinary experience sufficiently verifies. But the objection, though plausible, is not valid. Either the saline is not aptly selected, properly combined, or skilfully administered. There is ample proof of this outside of the testimony of Drs. A., B., or C. The evidence furnished by the innumerable invalids who resort to the aperient mineral springs of the world, is all to the effect that very insignificant portions of saline elements, frequently repeated, do get up with great uniformity an active cathartic effect. The amount in grains of the saline thus taken, *per diem*, is far below that which the physician usually orders at a single draught, and yet in the face of all this, and knowing how easily taken and pleasant in effect is the action of the mineral water when compared with the huge and nauseating dose of the apothecary, the old method remains in full vogue.

There are, as a matter of course, some states of disease in which rapid and strong explosions of medical energy are eminently proper, such as the sudden onset of a violent paroxysm of disease, as, for example, in migraine, or in any sudden seizures of extreme pain, where the hypodermic method is of course the best, or when the prompt production of a mechanical effect is desirable, as in emesis. But in each of these examples, it will be discerned that the objects are temporary, simple expedients to meet certain emergencies—not the carrying out of a systematic plan of cure for a protracted disease.

We are thus brought to this cardinal principle of therapy, deserving to be ever kept in mind, that as the almost invariable object of administering medicines is for the purpose of modifying deranged vital energy by the energy of the medical substances at our command, the applications of them should conform as nearly as practicable in grade and steadfastness of action to that of the disease. Whenever the morbid process shows continuity, so also should that of the agents brought to bear upon it. Or, putting the statement in an obverse aspect, as the administration of large doses of medicine at three- or four-hour intervals is acting on the rise, culmination, and decline principle of effects, such applications of therapeutical energy are justifiable only when the vital morbicity shows a like course. Is there any thing like this variability in the ordinary course of a single disease?

When the disease to be combated is inflammatory, or a febrile zymosis, or a structural lesion of some organs, or simply a functional derangement, more or less durable; or when the principle of therapeutical management clearly appears to be to keep all the outlets of the body in grade of action somewhat in consonance with the rapidity of molecular waste, the aim of the physician, it appears to me, should be to render the influence of his remedies far more uniform and continuous than he now does, or more like that of the disease. A better congruity in these respects is a comparatively easy matter, as it involves simply increased division of doses and of their periods of administration.

SUPPOSED DEATH BY CHLOROFORM.

By R. A. KINLOCH, M.D.,
of Charleston, S. C.

It is desirable that there should be recorded every death attributable to either of the anæsthetic agents in use, for it has hardly been settled that one of these agents should be universally employed because of its immunity from danger. In certain sections of our country and of Europe, chloroform is still the favorite article used, for its general adaptability and because in the largest experience it has proved safe as well as satisfactory. In other sections there is a strong prejudice against chloroform, and a belief that ether is entirely free from danger. I have, in an experience of over thirty years, never had occasion to distrust chloroform, and have never until now seen a death attributable to its administration. From very many experiments and observations, however, I have been led to believe that ether is less apt to be followed by nausea or by great depression of vital power. My rule of practice then, in late years, has been to employ chloroform in surgical and obstetrical practice, except in operations necessarily protracted, or where nausea and vomiting would be prejudicial to the condition of the patient. I am inclined to doubt if the death, in the case which follows, can be attributed solely to chloroform. Fright, terrible anxiety, a peculiar nervous organization, and an exalted moral sensibility, may have had much to do with the sad termination. But I prefer reporting the case and leaving it to the verdict of the profession.

Further interest attaches to it from the fact that the secular press has circulated through the country the grossest mis-statements regarding the case itself, and the conduct of the physicians connected with it. I will notice and correct only two of these. It has been falsely stated that assistants were introduced into the operating chamber of the patient against her wishes, and while she was insensible from chloroform. The truth is, the consent of the lady was freely given, because she knew that the assistants were necessary. Her only desire was that she should be chloroformed before they were introduced. Next, it has been affirmed that the cause of death was suppressed in order to shield the physicians, and to prevent a coroner's inquest. The truth is, the death (although the matter was rather doubtful) was at once assigned to the chloroform. This was announced frankly to the family of the deceased and to others. Moreover a mortuary certificate of death from *chloroform narcosis* was handed to the City Registrar, in order to obtain a permit for burial.

Case.—On the 7th of May, 1882, I was called to attend Mrs. L. R., who had long been an invalid, and been attended before by two very worthy practitioners of this city. She was aged about forty, married, a mother of two children, the last being six years old. I found her thin, anæmic, unable to exercise without much backache; never sleeping well at night; having usually prolonged and profuse menstruation—in the intervals, much leucorrhœal discharge; great bearing-down sensations, with vesical and rectal tenesmus; difficult digestion and constipation. These symptoms, in part, pertained to her since the birth of her first child, but had been more continuous and severe for several months past. There now also is complaint of severe paroxysmal cough, with the physical signs of sub-acute bronchitis on both sides of the chest. The pulmonary symptoms Mrs. R. attributed to a recent cold. She said she had sent for me chiefly to relieve her of the trouble which she had had during many years, and which made life a burden to her. She said she knew the disease to be uterine. Other physicians had treated her for this; but she was in hope that a radical operation might relieve her. There was prevailing an epidemic of whooping-cough, and the children in the house had suffered. Mrs. R. had formerly had this disease, but the character of her pulmonary symptoms led me to believe that she was to some extent suffering from the "epidemic constitution of the atmosphere." She was anxious for a thorough examination; so, after prescribing for her cough, I appointed an early day for the purpose, and in due time discovered a left lateral fissure of the cervix, reaching to the cervico-vaginal junction; also an elongated and enlarged cervix, a prolapse of the bladder, and prolapse and partial retroversion of the uterus. I gave as my opinion that much could be done by treatment, both local and general, but that, first of all, the cough must be relieved, and the digestive organs improved. In time, I proposed to apply local remedies to the uterine and cervical cavities, and to close the fissure by operation. Mrs. R. was intent upon an early operation, as she said she had too long been trying palliative remedies. I could with difficulty persuade her that these radical means must for a time be postponed. After about a month's general treatment, part of which time I was absent from the city, Mrs. R. had so improved that she again renewed the question of operation, saying that her cough did not now affect her, and that she wanted to be attended to before leaving the city for a summer's vacation. While regarding her as a rather bad subject for any operation, I, nevertheless, thought the cervical fissure could be closed without risk, and that, by the use of a pessary, she could be enabled to go comfortably into the country.

June 19th was appointed for the operation. Mrs. R. had always been exceedingly sensitive as to the matter of personal exposure, and I readily consented to give the chloroform only in the presence of female attendants. When the request was made for the patient to get upon the table, she became much excited, and could scarcely be comforted and assured. She shrank back as one having a feeling of impending danger. I subsequently learned that she had had a presentiment of death, and went so far as to write out requests she wished fulfilled after death. I mention these facts to illustrate the nervous condition of the subject, as with many it may be considered as having something to do with her sad end. The chloroform was given upon a towel folded funnel-fashion. The towel was at first held a little distance from the face, until the patient grew accustomed to the vapor and was habituated to

the proper inhalation. The usual period of excitement came on, with some struggling of the arms and rolling of the body. One of the female attendants helped to control these movements, and in a short time relaxation began to be evident, with the slightest stertor of breathing. Less than three drachms of chloroform had been used. I at once suspended the chloroform, passed the towel over to the nurse, who was at the bedside, and a little removed, and asked her to hold it where she was. I felt no apprehension about the patient, and moved to the door separating the chamber from the parlor, and called to Drs. Simons and Pelzer, my assistants, to enter. I now took my position at the foot of the table, while my assistants remained at the side, and began to put the patient into the semi-prone and lateral position for operation. I little thought that during the few seconds of absence the cumulative effects of the drug would be exhibited. Glancing at the face of the patient, I suddenly discovered that it was cyanosed, and the eyes staring and fixed. I called to Dr. Simons to notice if the breathing was right, and almost simultaneously we both advanced to the patient's head. I saw that the respiration was embarrassed, and heard a gurgling noise coming from the presence of mucous secretions in the bronchii. Dr. Simons raised the head of the patient, and turned the body partly over into the supine position. I threw up the windows, dashed cold water upon the face and chest, slapped the surface smartly, depressed the head, while the body and lower extremities were raised, injected brandy, and subsequently liquor ammonia and brandy, subcutaneously. Towels were wrung out of very hot water and applied over the cardiac region. Used galvanic battery as soon as this could be secured. Finally, noticing that the respiratory movements were now entirely arrested, also the action of the heart, while the veins of the neck were greatly distended, I opened, first, a vein at the bend of the arm, and afterwards the right external jugular, hoping that, by removing some of the dark blood from the cavities of the heart, this organ would have a better chance for contracting. All to no purpose—the heart remained paralyzed, and we had soon to realize the fearful fact that death had supervened.

A CASE OF STRANGULATED INGUINAL HERNIA WITH AN UNUSUAL COMPLICATION.

BY GEORGE McCLELLAN, M.D.,
SURGEON TO THE PHILADELPHIA HOSPITAL, ETC.

ON April 6, 1882, I was summoned at 6 P. M. by Dr. Tuttle, one of my assistants at the Philadelphia Hospital, to see a patient who had just been admitted, in a state of prostration without any history, the man being a Hungarian and unable to speak any intelligible language. I found the patient's pulse fairly good—80, I believe—with no apparent increase of temperature. The countenance wore a slightly anxious expression. There was hiccough, and at intervals a little vomiting of a glairy mucus. A large bulging protrusion existed in the right inguinal region. There was no testicle to be found outside of the tumor, which was of oval shape, and about four inches long, extending from a point corresponding to the internal abdominal ring to the raphe of the scrotum.

Upon percussion, an uncertain impulse was elicited, suggesting a fluid accumulation. There was no resonance, but a doughy feeling, giving the impression of a bunch of omentum. There was no impulse on coughing. There was no discoloration of the integuments, and no tenderness on pressure or manipulation. The abdomen was distended, and the patient complained of pains about the umbilicus. From a fellow-patient, who could speak a little Hungarian, it was ascertained that the bowels had not been moved for five days, and that the tumor had existed for two years, having been caused by an injury while riding on horseback. It had not increased in size lately, and the patient did not feel any new uneasiness in or about it. He felt the effect of constipation only, and had repeatedly tried to defecate without avail before coming into the hospital. Taxis had no effect in overcoming the protrusion.

I considered carefully the symptoms for strangulation, *i. e.*, the hiccough, the tympanites, the umbilical pain, and the absence of fecal discharges for five days, and the absence of impulse on coughing; and those against strangulation, *i. e.*, the pulse, the temperature, the absence of discoloration, and the freedom from tenderness in the region of the groin, the patient lying on his back without drawing up the legs to relax the part, and the strong probability of a testicle undergoing some cystic degeneration, etc. The weight of the latter symptoms seemed to justify the conclusion to administer oil by the mouth and by the rectum, to apply mush poultices over the abdomen, and to give stimulants and milk, and wait for further developments. On the morning of April 7 I found that the man had had an evacuation of the lower bowel by the enema, but that he had not retained anything whatever by the mouth. His pulse and countenance were good, although he was perceptibly weaker, and he vomited while I was in the ward for the first time what looked like stercoraceous matter. I therefore decided to operate without further delay, as it was evident that he was suffering with intestinal obstruction. The symptoms in other respects were unchanged from the condition of the evening before.

As soon as the patient was etherized, I cut down upon the tumor in its long diameter, laid open the several layers of fascia upon a grooved director, coming, finally, after ligating one small vessel, to what had the appearance of a cyst wall. The testicle could not be clearly defined. I broke up adhesions which were everywhere about the mass, and feeling sure that fluid was contained in it, I inserted an exploring needle, which showed that a serous fluid was within. A hypodermic syringe was then introduced, and readily withdrew an amount of bloody serum. The fluid looked like that of a hydrocele. I incised the sac, and at least four ounces of fluid escaped. Through the walls of the sac a bunch was felt at the upper portion, which was conjectured to be the testicle; but on further slitting up the sac, a large knuckle of intestine was found, with its mesen-

tery doubled upon itself, and presenting all the indications of having been incarcerated for some time. There were adhesions everywhere about its neck, attaching it to the sac, and a more recent constriction immediately above. The constituents of the cord and the testicle were found imbedded in a thick layer of tissue closely adherent to the inner side of the sac, the testicle itself being atrophied. After nicking the restraining bands about the neck carefully with a hernia-knife, the gut was restored to the abdomen. The walls of the gut were dense and thickened, and although congested had no indications of ulceration. The large mass of peritoneum being thickened and indurated, and having the cord and testicle intimately adherent upon its inner portion, was included in a stout double ligature and cut away. I united the edges of the wound with deep interrupted wire sutures, taking care to include the pedicle of the peritoneum in one of them. A carbolized sponge was trimmed so as to fit closely over the parts, and firmly applied with a spica bandage. The patient died eight hours after the operation from shock and peritonitis, having with great difficulty been brought out of the anæsthetic state, and having received every possible attention to sustain the powers of life.

The autopsy showed that a portion of the ilium (about fourteen inches long) was enlarged, indurated, and deeply congested. The point of strangulation was clearly marked. Very little fluid was found in the peritoneal cavity. The pedicle of peritoneum and the cord completely blocked up the internal ring.

In view of the facts above related, I am inclined to believe that the tunica vaginalis testis had always communicated with the peritoneal cavity of the abdomen before the receipt of the injury on horseback which the patient referred to, and that the intestine at that time found its way into the inguinal canal behind and above the testicle, and remained there. The wasted condition of the testicle was probably due to pressure on the cord, caused by the incarcerated intestine. The bands of lymph, which were remarkably firm and resisting about the neck of the hernia, opposed the return of the peritoneal fluid into the abdomen, although it is doubtful if there was not a passage existing before the strangulation. The extraordinary amount of peritoneal fluid contained in the sac was a most interesting feature of the case, as it rendered it very difficult to form a correct diagnosis. The unyielding nature of the walls of the sac is often found in an incarcerated hernia, but the apparent absence of the testicle in this case, and the character of the tumor, with its imperfect history were most misleading.

MEDICAL PROGRESS.

Sulphide of Calcium as an Antisuppurative.—Dr. Andrew H. Smith, Chairman of the Committee on Restoratives of the Therapeutical Society of New York, furnishes to the *New York Medical Journal and Obstetrical Review* for June, 1882, a report of the committee on the use of sulphide of calcium for the purpose of preventing or diminishing suppuration. After giving the experience of several members of the Society, Dr. Smith concludes his report as follows: Judging from this limited number of cases, it would seem that we are warranted in concluding that in many cases of suppurative affections, ranging from the small pustules of acne to extensive suppurating surfaces, an appreciable, and often a very marked, benefit is derived from the use of the calcium sulphide, suppuration which would otherwise take place being averted, or the quantity and duration of an existing discharge being lessened. At the same time its action is not uniform; and in many apparently favorable cases it will fail entirely. The drug is somewhat prone to irritate the stomach, and this circumstance affords an indication for small doses frequently repeated instead of larger ones at longer intervals. One-tenth of a grain every two hours in acute cases will generally secure the full therapeutical action of the drug, but larger doses may sometimes be required, and some patients will bear well a grain three or four times a day. Even in small doses the sulphide will occasionally produce headache, and the patient is usually more or less annoyed by eructation of sulphuretted hydrogen.

Coloboma of the Choroid and Optic Nerve Sheath.—Dr. A. H. Benson (*Dublin Journ. of Med. Sciences*, March, 1882) describes two cases of coloboma exhibited at a recent meeting of the Medical Society of the King and Queen's College of Physicians. Ophthalmoscopic drawings are appended. Both cases were discovered while the writer was assisting Dr. Fox in examining, for statistical purposes, the eyes of the deaf mutes in the institutions about Dublin. Both patients were deaf and dumb.

In the one case there was, in each eye, coloboma of the choroid without implication of iris or disk. In the other case there was in the right eye an enormous coloboma of the optic nerve sheath—the largest on record—associated with, but separate from, a very small coloboma of the choroid; and in the left eye a smaller coloboma of the optic nerve sheath, without coloboma of either choroid or iris, but in the position of the junction of the lips of the fœtal fissure a disturbance of the pigment layer, suggesting the idea of a raphé, where the trouble just stopped short of the production of a coloboma.

From these cases the writer concludes:

1. That coloboma of the choroid may exist without corresponding coloboma of the iris.

2. That closure of the fissure in the pedicle (optic nerve) takes place independently of the fissure in the optic cup.

3. That the fissure may close in the optic nerve and remain open in the bulb, or may close in the bulb and remain open in the nerve, or may remain open in both bulb and nerve, closure having taken place in the interval between the two colobomata.—*Ophth. Review*, June, 1882.

Excision of Pylorus.—Henck, of Heidelberg (*Wien. Med. Blätter*, May 18, 1882), at the Congress für Innere Medizin, tabulated the history of twelve resections of the stomach. One, which recovered, was performed in a case of stricture of the pylorus following perforating ulcer. The remaining eleven were for the removal of cancerous growths; four of these recovered from the operation; out of the recoveries, three patients are still alive and free from any recurrence; the fourth is known to have died four months after the excision, from a return of the disease. Czerny's patient, referred to in Internat. Med. Congress, who gained eleven pounds within six weeks of the operation, was ten months after the operation quite well, with

no symptoms of recurrence of the disease.—*Maryland Med. Journ.*, July 1, 1882.

STRETCHING THE OPTIC NERVE.—The first attempts at stretching the optic nerve were made by Wecker; in one case without success, in the others the result has not been stated. KUMMEL (*Deutsche Med. Wochensch.*, 1882, No. 1), by experimenting on animals, and on the cadaver, satisfied himself of the harmlessness of the operation, which consisted in passing a blunt spatula-shaped instrument through an opening in the conjunctiva at the inner border of the cornea to the point of insertion of the optic nerve, after tenotomizing the internus. Kümmel prefers passing a blunt strabismus hook in between the inferior and externus. In seven cases in which he performed the operation there were no serious consequences. Observations on the dead subject showed that tractions on the nerve produced an action spreading as far as to the entrance of the optic tract into the cerebral substance. In a patient who had been under treatment for a long time with iodide of potassium and strychnia, the stretching of the optic nerve produced an improvement. The other cases were unsuccessful, although the operation was not followed by any bad results. He recommends a trial of this operation in slowly progressing atrophies in which some qualitative light sensation still remains.—*Edinburgh Med. Journ.*, April, 1882.

A NEW FRACTURE OF THE ASTRAGALUS.—DR. SHEPHERD, Demonstrator of Anatomy at the McGill College, Montreal, has recently met with four specimens of a hitherto undescribed fracture of the astragalus. In each bone the injury consisted in the fracture of the outer projecting edge of the groove for the tendon of the flexor longus pollicis. In three of his specimens the union was fibrous, in the fourth it was bony. He has failed to produce the fracture experimentally, but he advances the view that it is produced by a twist of the foot outwards while in the position of extreme flexion at the ankle-joint, and further suggests that it may be one of the lesions in cases of severe sprain of the ankle-joint, and that it may account for the impairment of motion sometimes met with after what is believed to be only a sprain. All of his specimens were obtained from the dissecting-room, and he was unable to get any clinical history to throw light on the mode of production, or results of the injury. We should imagine that the diagnosis of this injury would be very difficult, if not altogether impossible.—*Lancet*, July 1, 1882.

THE ABSORPTION OF IODOFORM.—In view of the great discrepancies as to the fatal dose of iodoform, ZELLER undertook some experiments to determine how much and how rapidly iodoform was absorbed, and gave his results at the meeting of the Congress of German Surgeons at Berlin on June 1, 1882. Various opinions are held as to the changes which iodoform undergoes when absorbed, Moleschott believing the effects to be due to nascent iodine, Benz to the union of iodine with a metal, and others to a compound of iodine and albumen. According to Zeller, who estimated the iodine excreted through the urine, iodoform is only slowly and imperfectly absorbed from the intestine, while its excretion may last more than three weeks. It is rapidly absorbed from the abdominal cavity, under which conditions the bile coloring matters are also found in the urine, accompanied by severe toxic symptoms which are equally severe when the iodoform is applied to the surface of wounds: as iodoform accumulates in the blood it produces a cumulative action, so its results cannot be foretold. Iodoform is no more soluble in serum than in water.—*Deutsche Med. Wochen.*, June 17, 1882.

ACTION OF ALCOHOL ON DIGESTION.—BUCHNER (*Deutsche Arch. f. klin. Med.*, xxix. p. 537) has made a series of experiments on this subject by adding alcohol to artificial digestive fluids in a flask, and also by washing out the stomach six hours after a meal, and ascertaining what proportion of the food remained undigested when alcohol had been given or not given along with the food. He finds that alcohol up to 10 per cent. strength has no influence as such upon artificial digestion. When added so as to form 20 per cent. of the digestive fluid, it slows artificial digestion. In larger proportions it completely arrests it. Beer when undiluted completely stops artificial digestion, and when diluted slows the process. Red and sweet wines have a similar action, while white wines even when undiluted only slow digestion. Both beer and wine hinder digestion in the stomach even in small quantities. When the processes of absorption and secretion are already disturbed wine and beer may completely arrest digestion. They should, therefore, be given with the utmost caution or completely withheld in cases of gastric catarrh.—*Practitioner*, July, 1882.

THE CHOICE OF DRAINAGE TUBES.—M. NICAISE (*Rev. de Chir.*, Dec. 1881) points out the importance of using non-irritant India-rubber drainage tubes in the dressing of wounds. He gives the following directions:

The tube should be short and wide, and should not be in contact either with the bone or the ligature of the chief artery.

Tubes are gray, black, or red. They should be made from laminæ of pure caoutchouc cut with the saw, vulcanized, and desulphurized. Good tubes may be recognized by (1) the transverse markings left by the saw; (2) their lightness—they should float on water; (3) their strength—they should bear being tripled in length without breaking.

Bad tubes are made from sheets of paste made up with shreds of caoutchouc, zinc white, minium, etc. If gray, they remain so after being dipped in an alkaline solution. Gray tubes have not been freed from sulphur, and this separates out and irritates the wound; they should be avoided. Red tubes, which have been desulphurized by soaking three hours in a hot 10 per cent. solution of carbonate of soda, may be safely used. Black tubes answering to the above tests are the best of all.—*Practitioner*, July, 1882.

INJECTIONS INTO THE SUBSTANCE OF THE LUNG.—DR. E. FRANKEL (*Centralb. f. d. Med. Wissen.*, June 10, 1882) has injected acetate of alumina, carbolic and boracic acids, and iodoform into the substance of the lungs of rabbits, by means of an ordinary Pravaz syringe, to which, in order to prevent hemorrhage, he had attached slender needles. The number of injections varied from one to six daily, this number being sometimes given on many successive days, at other times with a few days' interval. The animals were apparently very little affected by the procedure; some even gained in weight. After they were killed, there were found indications of extravasation, proliferation, and infiltration in the pleura, and in the lung tissue. These were all progressing towards recovery, either by absorption or by the formation of cicatricial tissue. The author suggests that in cases of disease of the apices, injections might with advantage be made both in the affected parts and in the healty tissue adjoining, to change the character of the inflammation in the first situation, and in the second to increase its powers of resistance, and by the production of cicatrices, to lead to the formation of a barrier, which should arrest the extension of the morbid process. He recommends his method also in putrid bronchitis and gangrene of the lung. In the case of one patient, who expectorated

fetid sputa, he made six injections, using latterly 3 grammes of a 5 per cent. watery solution of carbolic acid; not the slightest reaction, not even a single cough, followed this little operation, but there remains the fact that the odor of the sputum was not in the least degree modified.—*Glasgow Med. Journ.*, July, 1882.

The Treatment of Epilepsy.—Künze (*Neurolog. Centralb.*, January, 1882) treated thirty-five patients suffering from epilepsy, with completely successful results in nine of them, by means of curare. The published cases show that complete recovery occurred in very severe cases of epilepsy, even when the disease had existed for years, and the intellectual faculties had become affected. Acting upon these results, Prof. Edlesfen has investigated anew the effects of treatment by curare in certain grave cases of epilepsy, since the effects of treatment whether by the bromides or by atropia are not so entirely satisfactory as to render all other methods superfluous. He employed the formula recommended by Künze, filtering the solution before injecting it—Curare, 0.5 gramme; aq. dest. 5.0 grammes; acid. hydrochlor. gtt. 1, digere per xxiv. horas, de infiltra. Of this solution, one-third is to be injected every five days; as a rule it neither causes much pain nor any noticeable reflex symptoms; in no case did it cause any toxic phenomena; still it is necessary to ascertain the trustworthiness of the preparation of curare before employing it. Two cases of hystero-epilepsy were not benefited by this treatment, whilst of thirteen cases of true epilepsy, the majority characterized as severe cases of old standing, six were not permanently improved, whilst three were completely, and, up to the present, permanently cured. Three other cases, although not cured, were distinctly improved, the attacks being interrupted for several months. One case is still under observation, and promises to be successful. Prof. Künze recommends that the treatment be given up if there be no sign of improvement after the fourth or fifth injection. (*Centralb. f. klin. Med.*, 1881; *Med.-Chir. Rundschau.*, October, 1881.) Dr. G. Ferraud sums up the recent results of treatment with bromide of potassium at the Salpetriere (Paris). The cases of eighty-nine female patients are analyzed as follows: 13 per cent. very greatly benefited; 15 benefited; 18 slightly benefited; 12 not benefited. Minimum daily doses of 5.6 grammes for women and 6.8 for men are recommended. Legrand du Salle continues to give the salt on six days of the week for the first three months after the fits have ceased for a year, and afterwards on three successive days in each week. Arsenic is found useful in acne produced by the bromide, and to avoid serious weakening of the memory coffee is ordered for all patients whose daily dose is more than 7 grammes. —*Cincinnati Lancet and Clinic*, July 15, 1882.

The Radical Cure of Hernia.—Schwalbe, of Margburg, read a paper on this subject at the Berlin congress of German surgeons, on May 31st, in which he recommended the already well-known method of injecting 70 per cent. alcohol into the neighborhood of the hernial sac, as entirely harmless and very effective, and he reported thirty cases in which a radical cure was effected. Occasionally it is necessary to repeat the injections very frequently, as many as one hundred and fifty having been used, especially when the horizontal position can not be retained; the hernia should be kept reduced during the treatment by a suitable truss. Schwalbe believes that this method is preferable to Heaton's, as in the latter the white oak extract, being less diffusive, must be injected directly into the sac.

Ranke stated that he had employed Schwalbe's method in more than one hundred cases, and was not very favorably disposed towards it: the injections are always very painful and often leave serious infiltrations. There was no doubt that in children it would hasten the normal closure of the ring. Gussenbauer had employed this method in six cases, in none of which had a complete cure resulted.—*Deutsche Med. Wochen.*, June 10, 1882.

The Symptomatology of Bright's Disease.—M. Dieulafoy lately called attention to certain symptoms of Bright's disease (parenchymatous and mixed nephritis), of which too little notice has, he thinks, been taken. The most important of them is frequency of micturition, a symptom which, although frequently associated with polyuria, may exist independently of any increase in the quantity of urine. In some cases the symptom is very troublesome; the bladder has to be emptied twelve or fifteen times a night, and twenty or twenty-five times in each twenty-four hours, and this although the total quantity of urine may not amount to a pint. This symptom Dieulafoy proposes to term pollakuria, and it may be manifested in three forms. 1. An early form may attend the commencement of the renal disease, of which it may be indeed the earliest manifestation and of considerable diagnostic significance. 2. A late form, which attends the chronic stage of the disease which has commenced acutely. 3. A form in which the symptom is attended with great pain and distress, and is accompanied by tenesmus and spasm of the sphincter ani, lasting from three to eight minutes. Another symptom is irritation of the skin. M. Dieulafoy asserts that it is met with in one-third of the persons suffering from "albuminous nephritis," whether interstitial, parenchymatous, or mixed, and that it is especially frequent in women. This symptom is also met with in different forms. Sometimes it has the character of ordinary pruritus, and may be thus the initial symptom of Bright's disease, preceding for months any other inconvenience. It has been explained by uræmia, and has been attributed to an excretion of urea by the skin, but in one of his cases the symptom was not present, although a large amount of urea was excreted by the skin. In other cases the itching is much slighter, and is described as resembling the sensation produced by the contact of a hair with the skin. The last symptom to which attention was directed is that which is described by patients as the "fingers going dead." It is a sensation of formication or cramp, accompanied by such pallor that the part looks altogether exsanguine. It may last half an hour or so, and then disappear entirely. Rarely both hands are affected, and when it is bilateral and partial the area is always symmetrical on the two sides. It appears to be due to a true vaso-motor disturbance.—*Lancet*, July 1, 1882.

Excessive Mobility of the Uterus.—Grassi (*Lo Sperimentale*, Jan. 1882) thinks that this condition is much more frequent than is generally supposed, and is often mistaken for version. By itself, apart from other possibly co-existing alterations, it may give rise to manifold sufferings which increase with the rapidity and extent of the motions to which the uterus is subjected.

Excessive mobility of the uterus may be congenital; it may occur in nulliparæ; but usually it is due to laxity of the supports of the uterus, attributable to one or more child-births. In consequence of this condition, coition may become painful, conception be rendered more difficult, and pregnancy suffer interruption during the first three months.

The treatment consists in toning up the system, hydrotherapeutics, etc., and the application of a well-fitting ring-pessary. The diagnosis is to be confirmed by the immediate benefit derived from the pessary.

The author emphasizes that the condition is a purely clinical one.—*Am. Journ. of Obstet.*, July, 1882.

BONY OCCLUSION OF BOTH POSTERIOR NARES.—DR. T. B. WILKERSON reports a case of congenital occlusion of the posterior nares by a bony septum, in a child six years of age, which he perforated by means of a new and ingenious instrument, a revolving trocar and curved canula, the drill attached to cable-screw wire; the latter being elastic, allows the handle of the trocar to be circularly rotated, whilst the curved canula remains stationary, the slit in the posterior under surface of the tube and pliability of the wire render the retraction and withdrawal of the trocar easy. The drill point protrudes beyond the end of the canula half an inch, length of trocar and canula about four inches, length of handle two and a half inches; without this instrument the operation would have been impracticable. A very satisfactory result was obtained.—*North Carolina Medical Journal*, June, 1882.

A CASE OF PARTIAL RESECTION OF THE TEMPORAL BONE.—At the meeting of German surgeons in Berlin, on June 1st, GLUCK stated that, after having opened the carotid canal fifteen times on the dead body, he finally had an opportunity to perform the same operation on the living subject. The case was that of a man who had suffered for seven years from otorrhœa from the left ear, who, after being exposed to cold, was attacked with violent headache, convulsions, coma, facial paralysis, and collapse, with severe hemorrhage from the ear. A diagnosis of suppuration on the petrous portion of the temporal bone, and corrosion of the carotid artery was made; after an appropriate incision through the skin, the mastoid process was carefully chiselled away and the dura mater exposed and incised, when thirty grammes of pus escaped. The seat of the hemorrhage was not detected: the patient died.—*Deutsche Med. Wochen.*, June 17, 1882.

INCONTINENCE OF URINE IN THE FEMALE.—DR. FRANK, of Cologne (*Centralb. f. Gynæk*, March, 1882), has planned and practised a new operation for the relief or cure of cases where the sphincter vesicæ has been so injured as to lead to incontinence. He points out this condition often exists after a fistulous opening in the bladder has been closed, and that such cases are very difficult to manage. He treats the urethra as one would an over-dilated rubber tube, by cutting a piece out of its circumference, so that less contractile power is sufficient to close it. A narrow strip is cut out of the whole length of the urethra, rather more tissue being removed at the seat of the sphincter. The sutures are not to be taken out till about the eighth day. A case is given where this method was successfully followed.—*Glasgow Med. Journ.*, July, 1882.

COMMUNICATION OF THE STOMACH AND INTESTINE WITH THE PLEURAL CAVITY AND A FECAL ABSCESS.—Dr. Tielmans reports a case of this character in *Arch. f. klin. Chirurg.*, occurring in a boy fifteen years of age, who was tapped for pyo-pneumothorax; cure resulted in five months.—*L'Abeille Méd.*, July 10, 1882.

GANGRENE OF THE BLADDER FROM RETROVERSION OF THE GRAVID UTERUS.—The last number of the *Archiv für Gynäkologie* contains an interesting article on the above subject, by DR. G. KRUKENBERG, of Bonn. He points out that cases of rupture of the bladder, and of gangrene of the bladder, from retroversion of the gravid uterus, are identical in their pathology. When gangrene of a portion of the vesical wall takes place, its peritoneal surface may be, or may become, adherent to neighboring parts, and in that case the gangrenous bit (or layer) may be cast off, entire or broken up. If no adhesion be present, and the bladder be subject to distention, its wall will give way at the weakened spot; or the separation of the slough may lead to perforation, even without over-filling of the bladder. Dr. Krukenberg has only been able to collect ten of these rare cases, and to these he has added one observed by himself. The practical conclusions which he draws from them are these: When the catheter has been employed and the uterus replaced before the sixth day, exfoliation of a portion of the vesical wall has never been observed. If regular catheterization is begun before the tenth day, rupture of the bladder need not be feared. When retention of urine persists longer than this, either gangrene or rupture of the bladder may supervene, rupture being the more frequent. Rupture of the bladder may also take place suddenly, from great distention of the bladder, or from efforts even most carefully made to replace the uterus. If gangrenous portions of the vesical wall are cast off, it should be an indication to abstain from attempts to replace the uterus (lest rupture of the bladder should take place), and to treat the case by the induction of abortion.—*Med. Times and Gazette*, July 8, 1882.

A MODIFICATION OF THE VAGINAL TOTAL EXTIRPATION OF THE UTERUS.—Freund's operation has been placed in the background by the vaginal method of total extirpation of the uterus, but even the latter is not free from difficulties; especially the ligation and separation of the first broad ligament are laborious and tedious. Experience shows that the second ligament is always more easily disposed of than the first, because the uterus is separated from the first broad ligament, and can be drawn in front of the external genitals. P. Mueller (*Centralbl. f. Gyn.*, No. 8), therefore, proposes to make the ligation and division of the first ligament as easy as that of the second by in some way splitting the uterus, either inverted or simply drawn downward, into two symmetrical parts in a vertical direction. Then each half with its ligament can be easily drawn down and the first ligament as readily tied as the second. Hemorrhage cannot be considerable, there being no larger vessels to be divided; moreover, the division can be effected so rapidly that in any event the bleeding cannot long continue, or the halves may be compressed manually or the ligaments rendered tense by traction or torsion until the ligature has been applied.

The author has not had occasion to test the value of his theory in practice, but hopes that some one of his confrères may give it a trial.—*Amer. Journ. of Obstet.*, July, 1882.

RESECTION OF THE STOMACH.—At the Congress of German Surgeons in Berlin, in the discussion on this subject, it appeared that out of eighteen cases which had been operated on for resection of the pylorus, only three yet lived. Prof. Richter thought that a much less dangerous operation in the case of fibrous stricture would be to make a duodenal fistula through which the stricture could be dilated with bougies. To this Rydygier replied that all of the three cases on which he had so operated had died. Billroth said that only one in fifty or sixty cases of carcinoma of the stomach was suitable for operation, and the first case in which he attempted the resection the tumor proved to be a myxoma, and the operation was abandoned. He had made as many as twenty exploratory incisions in as many cases, and at no time with a fatal result.

Gussenbauer was of the opinion that the cases of fibrous stricture were much more favorable for operation than carcinomata.—*Deutsche Med. Woch.*, July 1, 1882.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE, ... $5.00.

SINGLE COPIES, ... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made at the risk of the publishers, by forwarding in REGISTERED letters.

Address, HENRY C. LEA'S SON & CO.,
NOS. 706 & 708 SANSOM STREET,
PHILADELPHIA, PA.

SATURDAY, AUGUST 5, 1882.

SOME TROPHIC LESIONS.

THAT certain areas of nervous matters have an intimate relation to the nutrition of parts innervated by them, is evident. Irritation or disease of such "trophic centres," as they are called, is followed by wasting or degeneration. Although not all of such supposed centres have been accurately defined, the facts warrant the location of one in the fourth layer of the cerebral cortex, one in the anterior cornua, and one in the gray matter of the posterior columns of the spinal cord. The special peculiarity of the anatomical elements in these trophic centres is the presence of the multipolar ganglion cell.

There appear to be trophic fibres as well as centres, or at least sensory fibres endowed with a trophic function. Injury or disease, even irritation, of these fibres, quickly affects the nutrition of the parts in anatomical association with them. The great fifth nerve offers us an admirable example of this endowment. It is well known that irritative or destructive lesions of the trigeminus will be followed by inflammation of the eye, ulceration of the cornea, eczemas and herpes of the skin of the face, etc. The history of these facts regarding the trophic functions of the fifth is interesting as showing the changes of opinion which have taken place. When the influence of the nervous system on nutrition came to be known, the condition of the eye following division of the fifth nerve, was referred to the injury done to the trophic fibres. Then came a period of doubt, finally of denial. It was shown—it was supposed—that the disease of the eye which occurred under these circumstances, was the result of mechanical causes; that particles of dirt adherent to the cornea and other injuries brought on the mischief witnessed, and that if the lids were sewn together to protect the eye properly, no lesions of any kind followed division of the fifth. For a time this demonstration was regarded as final, and the fifth ceased to be regarded as a trophic nerve. Recently, however, the subject has been examined afresh, and new and more accurately conducted experiments have demonstrated that no amount of care in protecting the eye from injury will prevent destructive lesions of this organ following injury to the fifth nerve.

The late war furnished numerous examples of the results which succeed to injury of the trophic nerves, and much of the information on this subject, now current, had its origin in the admirable monographs which record these observations. Experimental evidence has not been wanting, and the clinical experience is constantly enlarging, so that, now, trophic lesions from injury or disease of the nerve-trunks are amongst the most obvious of pathological facts.

The spinal trophic centres have been localized by disease. It was first observed that in some cases of paraplegia, rapid wasting of the paralyzed muscles and decline in their faradaic excitability occurred soon after the onset of the disease; and in other cases of paraplegia, no change ensued in the condition of the muscles. It was subsequently found that in the former the disease involved the anterior cornua of the spinal cord, especially of that part containing the multipolar ganglion cells. Several diseases exhibit these changes in perfection—notably *poliomyelitis anterior acuta* (infantile paralysis), *glosso-labio-laryngeal paralysis* (chronic bulbar paralysis), *progressive muscular atrophy*, etc. As disease of this group of cells in the anterior cornua has for its constant result wasting of the paralyzed muscles, the trophic centre is accordingly located there. It is a curious fact, however, that certain osseous, and also cutaneous, lesions proceed from disease of the gray matter in the posterior columns of the cord, about the apparent origin of the posterior nerve-roots. Some of the most interesting trophic lesions, having their origin in this part of the cord, occur in the course of *posterior spinal sclerosis* (progressive locomotor ataxia). Changes in the joints occur not unlike those which are due to some kinds of rheumatism. Facts like this strongly support the theory of the nervous origin of acute rheumatism. In locomotor ataxia, the changes are profound; the joints are deformed by alterations in the bones themselves, and luxations readily occur; the animal matter of the bones decreases, and hence fractures take place with little violence. A similar change in the bones is now known to occur in the chronic insane, and in this fact is the explanation of the fractured ribs which are so often

found after the death of troublesome subjects. In advanced cases of tabes, fractures occur spontaneously, by muscular action, merely, without any violence, and a number may happen in the same individual, as in the case narrated by Charcot of a tabetic woman who suffered several times dislocations of the hip and shoulder, and fractures of the extremities, dying at last by the rupture of an aneurism of the aorta. We should not, of course, fail to mention the fact that the first account of spontaneous fracture in the subjects of progressive locomotor ataxia appeared in the *American Journal of the Medical Sciences*, July, 1873, from the pen of Dr. Weir Mitchell.

The slowly-developing morbid alterations consecutive to lesions of the gray matter about the posterior roots, offer a strong contrast to those rapid changes which take place in the muscles when the multipolar ganglion cells of the anterior cornua are affected by disease. There is, as would indeed seem to be necessary, a constant ratio in the progress of the centric and peripheric alterations. In infantile paralysis the mischief done in the nerve-cells is accomplished in a few days; in locomotor ataxia the gelatiniform degeneration of the posterior columns occupies as many, or more, years. The whole round of an acute herpes zoster will occupy about two weeks, whereas certain pigment changes, as in a form of vitiligo, may be distributed over many years.

Besides those trophic affections in which an immediate relation between the central and the peripheral disease can be traced, there are, doubtless, many of reflex nature which cannot be directly connected. We know, of course, what decided vascular changes are effected by reflex irritation, but the mistake should not be made of confounding vaso-motor with trophic affections. A good illustration of a reflex trophic lesion is afforded by the ulcer of the duodenum, caused by a burn of considerable extent on the chest or abdomen. As all the world knows, the relation between these two conditions is, by many, regarded as accidental rather than causative, and hence its pertinency as a fact in this connection may be denied. There is, however, a causal relation, of the reflex kind, between a burn of the surface and a low form of pneumonia, which must be admitted to exist.

DR. KINLOCH'S CASE OF FATAL CHLOROFORM NARCOSIS.

THE announcement of another death from chloroform is of such frequent occurrence that it no longer excites any other remark than, why was not ether given? Notwithstanding the formidable list of fatal cases from chloroform narcosis, there are many physicians who cannot bring themselves to use any other anæsthetic. Chloroform, compared with other anæsthetics, notably with ether, is so much more pleasant to inhale, so much more prompt in action, and in some other respects so much more desirable, that these physicians are disposed to adhere to their favorite, rather than encounter the discomforts of other agents which may seem to be safer. The question of safety must, after all, be the prime consideration. Is ether so distinctly safer than chloroform that it must be preferred, notwithstanding it is far less agreeable? The comparison of an immense number of exactly parallel cases can alone decide this question. With the increasing use of ether, the number of deaths caused by it becomes greater. If yet greatly less than those caused by chloroform, it must be remembered that ether has been used in a considerably less number of cases. That the condition of anæsthesia is in itself a condition of danger, irrespective of the agent used to induce it, remains a fact, in spite of the improvements in the technical processes. To suspend the functions of animal life, and at the same time to enfeeble the organic functions, induces a state of such constraint, that little more is required to end life. Although there are differences in the toxic activity of the various anæsthetic agents, it yet remains to be demonstrated that ether is distinctively, under all circumstances, an absolutely safe anæsthetic. Assertions in regard to the superior safety of ether are abundant enough, but these are not demonstrated facts. For our own part, we prefer ether, not for itself, but because a general conviction exists that it is safer, a view in which we share, although the proof is not yet conclusive.

Dr. Kinloch, having used chloroform for years without an accident, and preferring its action to that of any other anæsthetic, was warranted in continuing to employ chloroform, provided there was suitable care exercised in the selection of the subject and in the administration of the vapor.

The method of inhalation used by Dr. Kinloch is as old as the practice of modern anæsthesia. An open cone formed out of a towel, and large enough to cover the mouth and nose, has been employed in millions of cases without accident. It was first proposed by Simpson, and has been used more than any other inhaler. Notwithstanding the antiquity of this practice, and although sanctioned by usage, we must condemn it as unsafe, as it is unscientific. When such a cone is placed over and above the nose and mouth, although several inches removed, the vapor of chloroform displaces the air, and hence, in a little while, only chloroform vapor is inhaled. If the rule, to use an admixture of chloroform vapor and air, in which the former is not in greater proportion than 3½ per cent., is a sound one, it is clearly violated in this arrangement. When the cone is first placed in position, after

being charged with chloroform, or after any addition of the anæsthetic, the air supplied to the patient is composed for the most part of chloroform vapor. Now, as the density of chloroform vapor is about four times that of atmospheric air, it is clear that the latter must be displaced more or less completely—probably for a time entirely—when the inhalation is thus conducted. Therefore, although Dr. Kinloch pursued the most usual mode of administering the anæsthetic, we regard the method as in a high degree unsafe, since it is necessary in the giving of chloroform to secure the admixture of air in right proportions. The proper proportion of the anæsthetic vapor to the air is three and a half per cent., and it is in the highest degree important to comply with this rule in the administration of chloroform. That Dr. Kinloch may have failed to secure a sufficient admixture of air, is quite possible, but there is an enormous experience to justify and uphold the method he pursued.

The measures of resuscitation practised have abundant sanction in professional usages. We venture a criticism on one point—the subcutaneous injection of brandy. This practice, now so common, is certainly improper in the case of cardiac failure from chloroform, ether, chloral, and other agents, derivatives of alcohol. Whilst all of these derivatives have peculiarities of their own, they have one effect in common—they all, after a period of excitement of longer or shorter duration, cause cerebral depression, and brandy is, so far, synergistic to chloroform vapor. As in this case, the heart and lungs labored, the superficial venous trunks being greatly distended, the subcutaneous injection of amyl nitrite, or of atropia, would have served a more useful purpose. We make these suggestions in the interests of those who may, at some future time, experience a similar misfortune, and not as a criticism of Dr. Kinloch, who, in the method of resuscitation, as in the administration of the anæsthetic, acted in accordance with the general professional experience. We are also bound to admit, that the practice of Dr. Kinloch may be supported by many more than will approve our own suggestions.

It is gratifying to note that the South Carolina Medical Society have ranged themselves on the side of Dr. Kinloch against the enemies who seek, in such a misfortune, to ruin the physician. It appears that the unfortunate case has found a hearing in the newspapers, and the physicians connected with it are judged with that severity which only malice, guided by the most profound ignorance, can suggest, and that which in itself is but an accident, which may happen to the wisest and most prudent medical man, is made to wear the aspect of an unprecedented blunder. It is, therefore, with real pleasure that we read the loyal and manly words of the committee appointed to draft resolutions to express the sentiments of the physicians composing the South Carolina Medical Society. The members of the medical profession may usually be depended upon to support a colleague if merely unfortunate. Nor is this only what Mr. Spencer calls "professional bias." They have sympathy for misfortune, and an honest detestation of those misrepresentations that would injure, if not destroy a reputation which is at the same time the evidence of work well done, and the promise of future prosperity. We unite with the profession of South Carolina, and of the whole country, in extending sympathy to Dr. Kinloch for this unpleasant accident, and for the injurious criticisms to which he has been subjected.

THE CHEYNE-STOKES RESPIRATION.

A CORRESPONDENT calls our attention to the term "Cheyne-Stokes breathing" as in frequent use, but in regard to which, readers are generally in the dark as to its meaning. He has looked for information on the subject through the ordinary sources of knowledge, and now asks our aid in clearing up the mystery. We enter on this task the more readily, since we have offended by the use of this mysterious phrase, and because it is a topic of interest apart from the apparent difficulty of its explanation.

The phrase—Cheyne-Stokes respiration—means, of course, the kind of breathing described by Drs. Cheyne and Stokes. The first reference to the peculiarity was made by Dr. Cheyne, so long ago as 1816. Dr. Stokes recalled this fact to the attention of the medical profession, in his classical work on diseases of the heart and aorta, thirty years afterward. He also contributed some additional facts, and hence his name is rightly honored by association with Cheyne's in this suggestive phrase—Cheyne-Stokes breathing.

The condition signified by this phrase is a peculiar irregularity of breathing, associated with certain morbid conditions. Not all kinds of irregular breathing can be so designated. Indeed, the term is already mis-used, and there is a growing disposition to include under it all kinds of breathing associated with irregularity and sighing. As described by Cheyne and afterwards enlarged upon by Stokes, the kind of respiration to which this phrase is properly applicable, consists in the following phenomena: A pause in the breathing—a complete suspension in the respiratory acts for a period of time, during which breathing might occur several times in the normal manner; then the resumption of respiration very feebly and slowly, and a gradual and progressive increase in the number and depth of the respirations, until the maximum is reached; and then again a gradual and progressive diminution, in the same order, in the number and depth of the

respirations, until a pause occurs. Thus the movements of respiration oscillate; from an extreme in which all the muscles are laboriously engaged, to a minimum in which the respiratory organs seem hardly to act at all, and then a period of repose or of apnœa of longer or shorter duration; to be followed again by the gradual rise to the maximum. During this time of cessation of breathing the arterial tension falls, the pulse quickens, the pupil contracts, there occurs a lateral conjugate deviation of the eyes, the face becomes pale, and the mind—the intellect and the general sensibility—are for the moment obtunded. On the other hand, during the period of maximum activity in the respiration, the arterial tension rises, the pulse slows, the pupil dilates, and more or less cyanosis of the face and extremities appears.

The morbid states with which Cheyne-Stokes breathing is associated consist of certain chronic affections of the heart and arterial system. Stokes laid much stress on it as a sign of fatty degeneration of the heart. It has been observed in cases of aortic insufficiency, especially when caused by the calcareous deposits of senility. The first case described by Dr. Cheyne was one in which atheroma of the vessels led to attacks of cerebral hemorrhage. Chronic arteritis, arteritis deformans, and cardiac lesions arising under the same conditions, are the chief factors. The irregularity of breathing which belongs to tubercular meningitis has been said to have the Cheyne-Stokes type, but there is merely distant resemblance—by no means identity. The irregular respiration occurring in the course of the nervous symptoms of chronic albuminuria approaches more nearly in characteristics to the Cheyne-Stokes breathing; but here again there is resemblance, but not identity.

Cheyne-Stokes breathing is of evil omen, as a rule. This view of its prognostic value is a necessary corollary from its pathogeny. Due to changes in the arterial tunics, which interfere with the normal supply of blood to the medulla, the respiratory centre functionates in a spasmodic manner. The special rhythm of the respiration, which it is the office of the respiratory centre to maintain, is, under these circumstances, perverted. The irregular evolution of the rhythmic force signifies the onset of fatal symptoms, for the damage done to the walls of the vessels must continue in an increasing degree to interfere with the circulation in the medulla. The numerous examples of irregular respiration, bearing a more or less close resemblance to the genuine Cheyne-Stokes breathing, have a prognostic importance determined by the associated and causative lesions.

THE SUMMER CHARITIES.

No one feature of our civilization is more striking than its charities. The lame and the halt, the sick and the wounded, and even the incurable are cared for with a kindness and tenderness unknown to heathenism. Of all these, however, the latest developed are in many respects the most remarkable. Hospitals are charitable necessities, but the summer charities, if we may so call them, are, as it were, charitable luxuries.

One of the earliest was the Children's Seashore House at Atlantic City, and any one who has seen the results in health and happiness there attained, must have felt that it was a happy thought that led to so much good. Similar in idea, but reaching a different class, is the Seaside Home for Invalid Women. The physicians whose poor patients have been at either of these homes, appreciate to the full the boon conferred upon them. To the weary, over-worked shop girl the cottage of the Women's Christian Association at Asbury Park, well named Sea Rest, is open, and hundreds enjoy there a week or two of restful, refreshing holiday. All of these charge merely nominal rates, made possible by the gifts of generous friends, and thus make them available for any of the honest, hard-working, and thrifty, whose purses, nevertheless, would not otherwise allow of such an expense.

Another similar form of hygienic charity, and, in its way, quite as delightful, are the various excursions especially for children, who in our close cities suffer daily, though often unperceived, martyrdom. These are often only for a day, it is true, but the good done by a single day's outing to a poor little city boy or girl, who has scarcely ever seen a green field or an unstunted tree, is greater than we think. It is to such a child an immense event, talked about for months afterwards—well-nigh a perennial pleasure, as well as a physical boon. The St. John's Guild and other similar societies are doing good service by such excursions. The Children's Country Week Association, and the *Tribune's* Fresh Air Fund, aim at a longer holiday, and are doing a vast deal of good, how much in the case of the former we have but lately pointed out.

Apart from all the good moral influences attached to such charities—and no one can read the letters to the *Tribune* without seeing that it is indeed twice blessed, and blesseth him who gives as well as him who takes—they are, from the physician's standpoint to be commended and fostered. Of course, harm is occasionally done by over-play or other indiscretions, but the healthful influences far outnumber the harmful. Many a life has been saved, and many another one prolonged and brightened, by the blessed summer charities.

TRANSACTIONS OF STATE MEDICAL SOCIETIES.

It is usually the case that the annual volume of State medical society transactions is delayed in passing through the press until the papers have lost their freshness, and the interest in their contents is dissipated, and this delay, strangely enough, is generally the fault of the contributors themselves, but if the society's welfare did not thereby suffer, perhaps no one would complain. The Michigan State Medical Society has just set a good example by issuing its annual volume of three hundred pages in a little over two months after adjournment, and we congratulate the Society and its efficient Secretary, Dr. George E. Ranney, of Lansing, upon being the first in the field with this year's proceedings.

SOCIETY PROCEEDINGS.

AMERICAN OTOLOGICAL SOCIETY.

Fifteenth Annual Meeting, held at Lake George, July 25, 1882.

(Specially reported for The Medical News.)

The Fifteenth Annual Meeting of the American Otological Society was held at the Fort William Henry Hotel, Lake George, N. Y., on Tuesday, July 25, at 10.30 A.M., the President, Dr. J. Orne Green, of Boston, in the Chair.

There were present twenty-nine members, and four by invitation, who were requested to participate in the discussions. Four new members were elected in the Society, and the names of five candidates for membership were referred to the proper Committee.

Morning Session.—After transacting the ordinary routine business, the Business Committee of the Society reported the bulletin of papers to be presented, in the following order:

Dr. O. D. Pomeroy, of New York, read a paper on

DRAINAGE TUBES IN SUPPURATIVE OTITIS MEDIA.

In children it is often observed that in suppurative otitis media the meatus becomes so narrowed that it is difficult or impossible to cleanse or treat the ear. Incisions of the meatus to enlarge the calibre had failed; incisions behind the auricle to open into the tympanum had also failed, when a small tube of India-rubber was introduced into the meatus. When the canal was nearly closed it became necessary to pass a probe through the rubber tube, catching it upon its end and stretching it, so that its size was nearly reduced to that of the probe, in which condition it could easily be passed in the canal well down to the tympanum. When in position the rubber was allowed to resume its natural form, which it accomplished by drawing itself into the canal when the probe was withdrawn. After wearing these for two or three days, larger tubes became necessary, which often could be introduced without the aid of a probe. If granulations or polypus of the tympanum required treatment after the canal became dilated, the tubes were removed for this special treatment, after which they were returned. The reason for the successful treatment by these tubes is, 1st, the protection afforded the walls of the meatus from the aqueous discharge; and 2d, the gentle pressure of the elastic and dilating rubber tube. By this pressure granulations or polypi rapidly disappeared. Cases which had defied other means of treatment rapidly recovered in three to six weeks with very few relapses. The best instrument for the introduction of the tubes was a cylindrical probe with four deep notches made in its extremity. A few illustrative cases were given.

Dr. McKay, of Wilmington, Del., asked if the cases had been followed up, and if relapses had occurred.

Dr. Pomeroy answered that relapses had occurred, but less than with other methods of treatment. He purposely avoided making holes in the side of the tubes, so as to isolate the walls of the meatus entirely from pus.

Dr. Orne Green praised the ingenious way proposed to produce drainage, pressure, and dilatation. He had used pledgets of absorbent cotton with glycerine, with good success, though the action was slow. The proposed method offered great advantages on account of its roundness, its elasticity and smoothness. In the treatment of such cases, however, drainage was not the most important; the chief aim to be desired was dilatation and pressure.

Dr. Pomeroy said that the irritation of the walls of the meatus depended upon pus, hence drainage became a very important factor in the treatment.

Dr. Seely, of Cincinnati, inquired what length of time it required to bring about dilatation.

Dr. Pomeroy answered, from two to six weeks, while every two or three days larger tubes could be employed.

Dr. Seely had not had special difficulty in treating cases of narrowing of the meatus by the cotton and probe. He felt certain that swelling of the meatus was due to the irritating effect of the discharge.

Dr. Howe, of Buffalo, said that he fully appreciated the advantages of the method as a means of dilating the canal, when contracted as described in the paper. He did not understand how such lateral pressure upon a polypus was any better than the usual methods of treating these growths. Immediate removal certainly produced the desired effect much more rapidly, and in doing so we gain also the enlargement of the canal.

Dr. Knapp, of New York, has used for the purpose of preventing retention of pus and closing of the canal, perforated flexible silver tubes with a flange. They are easily introduced and removed, cleansed and renewed. They may be worn for hours, days, or weeks constantly or with intermissions, according to circumstances.

Dr. Kipp, of Newark, has found that, in cases like those spoken of by Dr. Pomeroy, deep longitudinal incisions will remove the swelling of the external canal usually very speedily.

Dr. A. Mathewson, of Brooklyn, reported

A CASE OF ABSCESS OF CEREBELLUM, FOLLOWING OTITIS MEDIA MONTHS AFTER APPARENT CURE.

A case of chronic suppurative inflammation of middle ear, with mastoiditis, in a child of eleven years, apparently perfectly and permanently cured for months, when, after indiscretion in diet, vomiting occurred and other symptoms, which seemed at first due to gastric and hepatic disorders. After two weeks, during which there were no marked or certain symptoms of brain complication, the child died in convulsions, and an autopsy revealed abscess of cerebellum. There was pus between dura and tegmen tympani, but the bone was not carious. The ear and mastoid seemed healthy.

Dr. Kipp thought that the value of ophthalmoscopic examination in cases of suppuration of the middle ear was not yet fully appreciated. Since the publication of his paper on this subject, he had seen several cases of purulent otitis media, in which double optic neuritis was present, and, as far as he could now remember, death occurred in all of these cases, the operation for perforation of the mastoid process having been refused. Although absent in many grave cases of this kind, the

presence of optic neuritis must remove all doubt that the brain or its membranes are involved in these cases.

DR. ORNE GREEN inquired if there did not exist any symptoms, like headache, before the attack came on, which might have been indicative of some occult trouble in the brain.

DR. MATHEWSON answered, that no such symptom occurred, and he congratulated himself that the patient had been getting on so perfectly well.

DR. ORNE GREEN then mentioned a case where the patient had appeared to be entirely well from his ear trouble for six months; only moderate headache would appear intermittently. At the end of that period, sudden death occurred, caused, as he believed, by rupture of an abscess of the brain. He asked Dr. Mathewson if there was any apparently normal brain substance between the abscess and the bone.

DR. MATHEWSON replied there was.

DR. KNAPP observed that, since Dr. Kipp drew the attention to the occurrence of optic neuritis, dependent upon suppurative otitis, he had ophthalmoscopically examined every case of severe otitis purulent media that had come under his observation. He found that this combined occurrence was quite rare; but in some cases it is very marked and important, as in acute cases of suppuration with internal mastoiditis. It is found more pronounced in the eye of the same side than in the other. After the opening of the mastoid, the retrogression of the optic neuritis went *pari passu* with the progress of the recovery from the ear disease. He related a case in illustration of which he said: when the mastoid was opened, and a large quantity of pus evacuated, a place at the cranial side of the cavity was found soft on probing.

DR. C. S. MERRILL, of Albany, reported

A CASE OF ACUTE MIDDLE-EAR INFLAMMATION, WITH DEATH ON THE FOURTH DAY, FROM EXTENSION OF THE DISEASE TO THE BRAIN.

A man, thirty-two years of age, consulted Dr. Merril on November 7, 1877, complaining of a sense of fulness in the right ear and impaired hearing. The membrana tympani was found somewhat congested, otherwise normal. H. D. watch R. 2½″; L. 7′. Politzerized the patient two or three times, which increased hearing of watch to 4″, and further advised application of a leech to inner surface of tragus, and one to the mastoid, close behind the auricle, and daily Politzerizing. He did not see the patient again till the 10th; then learned that the leeching had entirely relieved the condition, so that on the next day (8th) the fulness had disappeared and hearing had become normal, and the patient went to his office, contrary to the orders of his physician. At 5 A.M. of the 9th, he was seized with severe pains, for which anodynes were administered, and on the following day Dr. Merrill was called in to see the case again. He found the patient suffering from severe meningitis; pulse, 160; temperature, 103½°; respiration, 28; delirious most of the time; membrana tympani bulging and greatly inflamed, as were the deeper portions of the auditory canal. A free incision of the membrana tympani, which was unusually thick and firm, evacuated a large amount of pus. The Eustachian catheter was used, and air passed freely through the incision. At noon of the 11th, the local inflammation of the ear greatly subsided, but the meningeal inflammation increased in spite of all treatment. Coma and death occurred at 6 P.M. Autopsy, eighteen hours after death: Evidences of meningitis and pus were found over the region of the petrous portion of the bone. There had been perforation through the roof of the tympanum, and underneath the dura were found a few drops of greenish-looking pus. The perforation of the tegmen tympani consisted of two or three small openings. There was no necrosis. No evidences of inflammatory product in the bone itself.

DR. NOYES inquired if the patient had ever suffered from vertigo.

DR. MERRILL replied he had never before complained of his ears, but at the autopsy the membranæ tympani were found very thick, and he had no doubt they had always been so, so that the existence of former ear disease was not improbable.

DR. PROUT spoke of the necessity of early incisions, as proved by the case reported.

DR. THEOBALD, of Baltimore, thought the case described by Dr. Merrill one of those in which active constitutional treatment was indicated. The liberal administration of calomel might have given the patient a chance of recovery. In reply to Dr. Merrill's question: "Could anything have been expected from it after the manifestation of such severe cerebral symptoms as described?" Dr. Theobald referred to the case reported by Dr. Buck in his work upon the ear, where the patient was in a comatose condition from meningitis supervening upon acute middle ear inflammation, and yet the liberal administration of calomel with inunctions of oleate of mercury was followed by rapid recovery. He also mentioned cases of his own recently published, which illustrated the good effect of this treatment under such circumstances.

DR. POOLEY, of New York, asked if Dr. Merrill thought it was good practice to inflate in acute and subacute inflammation of the middle ear.

As joining the discussion on this and the preceding papers, DR. READ J. MCKAY read a short paper on

AURAL POLYPUS, FACIAL PARALYSIS, MASTOIDITIS, AND CHRONIC MENINGITIS, WITH RECOVERY FROM THE TWO LATTER.

A case of a man, aged 22 years, who had been suffering seven or eight years from a running from the left ear, the result of a blow with the fist received eight days before the occurrence of pain and discharge from the ear. Lately there had been occasional bleeding. Examinations revealed the existence of a polypus, nearly filling the auditory canal, which was removed with Blake's snare, and the stump touched with a ʒij sol. of nitr. arg. Local treatment: instillations of sol. zinc. sulph. and acid. carbol. after syringing the ear. This treatment was persisted in for some time without removing entirely the granulations. The application of nitr. argent. produced considerable pain. He ceased coming for some time, and when he returned five months after, stated he had suffered from gastric fever. There was then left facial paralysis and continued pain in the left ear and the left side of head, relieved somewhat by the application of warm water and ʒij sol. arg. nitr. Four weeks later the patient reappeared, having been treated in the mean time by his family physician for "malarial neuralgia" for which quinia was freely administered. He looked very pale and weak, left mastoid swollen and tender. Leeches afforded prompt relief, and they were repeated ten days later; there remains constant pain in the head, with such continuous nausea and frequent vomiting that he could not retain nourishment. This was finally stopped by hypodermic injection of one-third grain of morphia. Ophthalmoscopic examination revealed the presence of well-marked left optic neuritis, and congestion of right optic disk. Minute doses of calomel were given, one-tenth grain every few hours, until slight ptyalism occurred. A gradual change for the better then took place, pain and tenderness over the ear and in the head disappeared, the swelling of the inner extremity of the meatus decreased, vision improved, and optic neuritis subsided. But the facial paralysis still

continued, also the discharge from the ear, and the granulation tissue could not all be removed. The question arises in his mind, when optic neuritis is found in these chronic aural cases with the persistent pain, usually indicative of meningitis, whether the optic neuritis is due to meningitis alone or to meningitis with brain disease.

Dr. E. E. Holt presented a paper on

BOILER-MAKERS' DEAFNESS AND HEARING IN A NOISE.

The opinion advanced by Dr. Holt upon "boiler-makers' deafness" and "hearing in a noise," was based upon the examination of forty men from the shops for making steam-boilers at Portland, Maine, and of all those who made the claim that they could hear better in a noise, amounting in all to over one hundred cases that had been examined, the investigation showed that the deafness incident to the boiler-makers was due more to the effects of the occupation upon the conducting apparatus of the ear than to the perceptive parts of the same organ, since they heard the tuning-fork, as a rule, as long or longer than the normal ear, even with the external auditory meatus closed. All men engaged in this occupation become more or less deaf, the degree and length of time elapsing before this occurs depending largely upon the tendency of the middle ear to catarrhal inflammation, which was excited by constant movements of the ossicles, and which, affecting the delicate joints, thereby producing anchylosis, was the cause of the deafness. In these and in other persons, who made the claim that they heard better in a noise, the apparent phenomenon was due to the more or less anchylosed condition of the ossicles, whereby more or less of the sounds given off in any noisy place were not received, constituting the deafness, and when the voice was raised, as it was invariably in such places, the sound produced by it was conducted by the sound transmitting apparatus with less confusion than by the normal ear, in which the ossicles must be in a to and fro movement, or else the innumerable noises would not be heard, and there would be no confusion of sounds.

Dr. Pomeroy inquired if the sound could not be muffled by putting cotton in the ear.

Dr. Holt replied that this only made the ear more sensitive.

Dr. Pomeroy remarked that if Dr. Holt's theory should prove true, it would change entirely the pathology of the disease in question.

Dr. Brandeis has had experience diametrically opposite from that of the author. He is professionally connected with large iron works, where nearly all the workmen are affected with more or less difficulty of hearing. This, in his opinion, is not due to the great noises, but to the draught and exposure to great heat and cold, in consequence of which nearly all are affected with diseases of the naso-pharynx, which extends to the tubes and tympanum, as well as the ossicles and membrana tympani. Owing to the chronic catarrhal condition, we have complete or partial anchylosis and thickening of the drum-head, which renders them less susceptible to the impact of sound waves. In a noise the impact of sound waves is more forcible, and consequently we will have vibration of the conductive apparatus which transmits the sound to the labyrinth. The voice is not elevated in proportion with the increased noise, and therefore the betterment in hearing can only be attributed to the increased movements of the parts acted upon.

Dr. Theobald mentioned having met with cases in which the tuning-fork, when placed upon the *vertex*, was heard louder in one ear, and then when placed upon the forehead was heard louder in the opposite ear. He had not been able to explain this result.

Dr. S. Theobald presented a paper on

COMPLETE CLOSURE OF BOTH EXTERNAL AUDITORY CANALS FOLLOWING CHRONIC OTORRHŒA.

Patient, 13 years of age, had an attack of scarlet fever when 4 years old, which left her with a purulent discharge from both ears. After it had existed for several years, the running ceased after the breaking out of an eruption on the head, as the parents stated, but deafness persisted. The occurrence of pain in the right ear led the parents to seek professional advice. Both auditory canals ended in a cul-de-sac, 2 cm. deep on the right side and 1.7 cm. on the left. Auricles normally developed, and outer half of the auditory canals presented the normal appearance, but in place of reaching to the tympanal membrane, each canal ended abruptly a little beyond the extremity of the osseous meatus in a smooth, firm, concave floor, covered with thin integument, continuous with and similar to that lining the outer portion of the meatus and presenting to the probe the unyielding resistance of a thick bony septum. Hearing greatly impaired, but the patient was not profoundly deaf. This condition has persisted more than ten years with no apparent change. From another case, recently under observation, he believes this condition to be due to periosteal thickening.

The discussion of this paper was postponed to the afternoon session, and the Society then adjourned to 4 P. M.

Afternoon Session.—The second session was opened by the President at 4 P. M.

After the ordinary business was transacted Dr. Theobald's paper was discussed.

Dr. Pooley had seen a case similar to the one related by Dr. Theobald. The closure, however, was only on one side. The obstruction in the canal was bony and covered with common integument. It was the final result of a long-continued otorrhœa and gave the patient no inconvenience. She came on account of a purulent otitis with extension to the mastoid on the other side, which terminated fatally. This case was published some years since in the *New York Medical Journal.*

Dr. Kipp thought that cases of bony occlusion of the external canal from otorrhœa were not as rare as the author seemed to think. He had lately had a case of this kind in a young girl in whom the canal was occluded by a bony structure covered with skin. He made a crucial incision in the skin and tried to perforate the bony structure with a drill, but failed. There was purulent inflammation of the middle ear on the other side, but the canal was of normal dimension.

Dr. H. Knapp read a paper on

THE TREATMENT OF AURAL POLYPI.

It is easier to remove large polypi from the ear than small ones, and they are much less likely to relapse. The reason is that large polypi invariably contract at their base, and become pediculated, and the narrow pedicle can be easily snipped off. The growth of a polypus can be easily demonstrated in the cases where, for instance, after squint-operation, a polypoid growth springs from the wound in the conjunctiva. Growing at first with a broad base, they are often treated with nitr. arg., only to become more irritated, while a little patient waiting may give a chance for removal of the growth by cutting its thinner pedicle with scissors, and no after-treatment but cleansing the eye is needed. The same refers to the ear, and a case, illustrative of the bad effects of removal of a small growth from the ear was given, where finally treatment was abandoned for more than a year, then to be followed by a most easy evulsion of a large polypus with thin pedicle. Dr. Knapp uses in order of frequency Hinton's forceps,

Wilde's or Blake's snare, Politzer's ring-knife, and O. Wolf's sharp-spoon. He uses by preference the forceps, and believes this to be free from the danger commonly attributed to it, because he does not resort to evulsion, before a pedicle is formed. Even if a polypus originates from the membrane lining the ossicles, the bone is probably carious, and its removal may be more an advantage than otherwise, and that a polypus can originate in the membrana tympani itself, he is not ready to admit, on account of the structure of that membrane, which resembles that of the cornea. For the treatment of smaller polypi or the roots of larger ones he uses alcohol and boracic acid, and finds that not only the abundance and offensiveness of the discharge is most effectually controlled, but also that the swollen mucous membrane shrinks more than by anything else. Frequently the alcohol contracts the polypi in such a way that they project distinctly and can easily be removed. His chief object in the treatment is: abstinence from repeated cauterizations, alcohol treatment, non-interference with granulations with a broad basis until they become pedunculated, and finally evulsion.

DR. THEOBALD stated that, after trying various applications to prevent the return of aural polypi, he had for some time placed chief reliance in a mixture of equal parts of boracic acid and oxide of zinc. He also mentioned that not long since upon traction with forceps upon a small polypus the malleus was drawn forth with the polypus, which was attached to it, but no evil effects resulted.

DR. POMEROY is convinced that no amount of cauterization will prevent the return of the growth. He is pleased with the results obtained in his practice from the use of the forceps.

DR. JOHN GREEN, of St. Louis, is in favor of revulsion, after changing the character of the polypus, for which he uses chromic acid applied directly to the polypus.

DR. KIPP stated that his experience with alcohol was very similar to that of Dr. Knapp. He, too, had come to the conclusion that in most cases, when the symptoms were not threatening, it was best to delay the removal of the growth until a pedicle had formed.

DR. BRANDEIS remarked that the leading indication in the treatment of aural polypi is the radical destruction of the base or roots. For this he preferred the galvano-cautery. He did not rate boracic acid very highly, and believed it only of service as boro-glycerine, and then it acts simply as an antiseptic.

DR. POOLEY thought that the evulsion of polypi with forceps was apt in some cases to set up an irritation which would extend to the brain, and related a case of his own which terminated fatally.

DR. NOYES regarded evulsion as perfectly safe and judicious when the polypus was developed from the external auditory canal, but believed it unsafe if it sprang from the tympanic cavity, when he prefers the snare. He uses nitric or chromic acid less than formerly. He uses boracic acid quite frequently now, and packs it in so as to completely fill the canal.

DR. PROUT stated that his experience with alcohol and boracic acid coincided largely with that of Dr. Noyes, but found that alcohol caused as much pain as any other applications. He thinks the advantage of the boracic acid treatment was largely due to pressure. A favorite application with him was glycerole of tannin.

DR. SEELY had never resorted very much to mechanical interference, but when he did so, he used the snare. He had used chromic acid several years and was probably the first to use it. This acid extends in depth and not on the surface as other acids do, hence its action is more free from danger. In using boracic acid, he packed the meatus completely. He called attention to the fact that polypi and granulations can be effectually dealt with by milder, safer, and more efficient means than we are inclined to think.

DR. J. ORNE GREEN preferred the use of the snare, and related a case, reported to him by the late Dr. Edward H. Clarke.

DR. R. C. BRANDEIS presented a paper on

EXHAUSTION VERSUS INFLATION.

He spoke of the disadvantages attending the use of the Valsalva method, the catheter, and of Politzer's air douche. In all of these it is impossible to graduate the degree of pressure employed, and therefore there is an increased difficulty of hearing and also more tinnitus and vertigo than before. By using compressed air he is able to regulate the force of the current of air employed, and thereby obviates some of the last effects. In many cases, however, these methods prove unavailing, and then he employs traction or exhaustion of air from the external meatus. This he does by means of a Siegle's speculum, which is attached to an exhausting syringe, which can exert any degree of traction desired. By carefully watching the excursions and appearance of the membrane and chain of bones, the operator is able to determine when further manipulation should cease.

DR. SAMUEL B. ST. JOHN, of Hartford, has used an apparatus, somewhat larger than that described by Brandeis, in cases of chronic catarrh, in order to give the ossicles a chance of gentle exercise analogous to that of the joints in chronic rheumatism.

DR. MATHEWSON reminded the Society of the method pursued by Dr. Pinkney, of New York, published some years ago in the *New York Medical Record.*

ORAL COMMUNICATIONS

being called for, DR. KIPP stated that he had very often found *deafness combined with synchisis scintillans of the vitreous.*

DR. KNAPP stated that in a marked case of this disease there was no ear trouble.

The different papers read at the meeting were referred to the Committee on Publication.

The following were elected

OFFICERS FOR THE ENSUING YEAR:

President.—DR. J. ORNE GREEN, of Boston.

Vice-President.—DR. J. S. PROUT, of Brooklyn.

Secretary and Treasurer.—DR. J. J. B. VERMYNE, of New Bedford.

Committee on Publication.—DRS. J. J. B. VERMYNE, C. J. BLAKE, and J. O. GREEN.

Committee on Membership.—DRS. JOHN GREEN, H. J. MILLER, and C. H. BURNETT.

The Society voted to meet next year the day before the annual meeting of the American Ophthalmological Society, and at the same place, and then adjourned.

AMERICAN OPHTHALMOLOGICAL SOCIETY.

Eighteenth Annual Meeting, held at Lake George, July 26 and 27, 1882.

(Specially reported for THE MEDICAL NEWS.)

THE Society met at the Fort William Henry Hotel, Lake George, New York, at 10 A.M., July 26, 1882, the PRESIDENT, DR. HENRY D. NOYES, of New York, in the Chair.

The Secretary announced the death of DR. E. REYNOLDS, of Boston, many years an Honorary Member of the Society.

The following is an abstract of the scientific work of the meeting:

July 26th.—Morning Session.

Dr. Charles Steadman Bull, of New York, read a paper on

PULSATING VASCULAR TUMOR OF THE ORBIT AND EYELIDS, TREATED BY ELECTROLYSIS.

The tumor occurred in a female child, who was admitted to the Nursery Hospital in September last. It had grown to its present very large size since the second or third day after its birth, when the mother first noticed anything out of the way. The temporal and zygomatic fossæ were pretty well filled by it, and the area of redness had been progressing steadily, mainly upon the forehead. The child was healthy, with the exception of the condition of the left eye. Free pressure on the arteries made no difference in the size of the tumor, but pressure on the carotid stopped pulsation. There was no murmur over the tumor. Several methods of treatment were taken into consideration by himself and other physicians, as tying the larger or smaller vessels, giving ergot, trying electrolysis. The latter method was sustained only by himself. At first ergot was given, under which the tumor gradually diminished in size, but the child being taken away from the hospital the treatment was not continued; and at the end of some months when it was seen again, the tumor was enlarging. He then tried electrolysis, employing from four to twenty-two cells on several different occasions, with the result in the end of a steady diminution in the size of the tumor.

The paper was discussed by Drs. Knapp and Green.

Dr. W. W. Seely, of Cincinnati, read a paper on

REMAINS OF THE HYALOID MEMBRANE, WITH ATTACHMENT TO LENS, AND DETACHMENT FROM THE PAPILLA.

Also a paper on

SEROUS EFFUSION INTO THE VITREOUS, CAUSING TOTAL TEMPORARY LOSS OF VISION, DUE PROBABLY TO MALARIAL POISONING; RECOVERY.

In the second paper, the patient was a man 33 years of age, previously free from disease or injury of any sort. About September 15, 1879, he noticed rather suddenly dimness of vision and floating bodies; was just able to read. Ten days later, vision being worse, he consulted an oculist, who it seemed told him the eye was full of blood. He was sweated by jaborandi, etc., vision remained about the same for six weeks, when it became still worse, and leeches were applied, and various remedies given. Remained about three weeks in a dark-room; continued to grow worse. Vision cleared up somewhat within six weeks, and still further under phosphorus. About the middle of February, 1880, vision totally lost in about two hours. Returning for treatment, leeches were applied and patient remained abed in dark-room about six weeks. May 1st, Dr. Seely first saw him; found a long-standing external squint of one eye with extreme amblyopia and no perception of light in the other formerly good eye, except the faintest by the most peripheric upper and inner portion of the retina after mydriasis. Pupillary reaction limited. With undilated pupil everything blank under ophthalmoscope; dilated, upwards and inwards in the extremes, traces of red reflex. He had never seen anything of the kind before. Concluded the vitreous was filled with effused serum, and so far as he knew there could be but one explanation—malaria, though there was no history of it. Patient went home July 20, V. $\frac{20}{20}$. No trace of any fundal disease, nor trace of floating bodies; and patient said what he had called floating bodies was a waving before the eye. No treatment. September next he again complained of vision having become somewhat smoky. In October seen again, vision rapidly returned to $\frac{20}{30}$, floating bodies perceived with difficulty by ophthalmoscope. Had a severe chill during this visit. Quinia given. April, 1882, he wrote that vision was about same as when he last saw the Doctor. No signs of kidney disease discovered, although patient complained of lame feeling in the region of the kidneys; quinia was again given.

We know, said Dr. Seely, that malaria produces a similar state of things in the kidneys, even a hæmaturia, and he was confident he had seen at least one case of effusion into the middle ear due to malaria. He asked if it was not probable that in the cases narrated, as in the kidney and bowels, the poison selecting the blood-vessels, prepared the way for the escape of the watery part of the blood, an effusion? The differential diagnosis between what was in this eye and a hemorrhage was not in his opinion at all difficult.

Dr. Read J. McKay, of Wilmington, Del., read a paper on

DISAPPEARANCE OF IRIS AFTER EXTRACTION OF CATARACT.

Male patient, aged 57, farmer and mechanic, of excitable temperament, was operated upon September 16, 1879, by Graefe's method of extraction, under anæsthesia, which he took badly and which caused great congestion of face and head. Excision of iris was immediately followed by filling of anterior chamber with blood; iris was teased out, leaving very little in the eye. Five or six hours after operation maniacal excitement ensued, lasting several hours.

Forty-eight hours afterwards, examination of eye showed anterior chamber filled with blood, nearly obscuring iris. Moderate iritis ensued. Six weeks after operation he could read with a $+2\frac{1}{2}$ lens.

Several weeks thereafter, whilst visiting him at intervals of several days, the iris disappeared, and no trace of it was ever seen afterwards. The entire capsule of lens was uniformily opaque with deposits of blood-pigment upon it corresponding to site of original blood deposits.

February 24, 1880, a secondary operation was done upon capsule, followed by very good result, permitting him to see moderately well. This continued for some months, when he was subjected to great excitement, when dense opacity of vitreous ensued, from which he did not fully recover, and the eye was practically lost.

The President thought the probable explanation of the case was a reduplication of the iris, a folding back of the ciliary processes; and Drs. Seely and Bullard related similar cases to which they thought the President's explanation applied also.

Dr. McKay also read a paper on

NON-PULSATING EXOPHTHALMOS WITH RECURRING THROMBOSIS OF ORBITAL VEINS.

Female patient, began at ten years of age to notice slight protrusion of right eye. It was more noticeable when angry and at time of menstruation. It increased very slowly up to time of marriage, between twenty-one and twenty-two years of age. During pregnancy no material change occurred, but during her three labors, which were severely straining, it grew rapidly larger and worse. At time of second labor several nodules of enlarged veins first appeared at upper inner angle of orbit.

February 17, 1881, she first visited me at the suggestion of her family physician, Dr. L. P. Bush, of Wilmington, Del. Then the protrusion of the right eye was three-quarters of an inch beyond that of its fellow. The right upper eyelid was greatly enlarged and congested (to double its usual size). The right orbital region was much swollen and congested. Her disfigurement was so great that she covered her face well when out of doors to prevent people staring at her. Ex-

amination failed to discover anything abnormal about the nose, antrum, or mouth; no pulsation was felt, and none detected by stethescopic examination. Told her the protrusion was due to enlargement of orbital veins behind the eye pushing it out of orbit, and advised non-interference at that time. She then told me Dr. Agnew, of Philadelphia, had three years previously examined her and given the same opinion.

Early in April following, eversion of right lower lid caused her to send for me. It was easily reduced. Some days later I learned that Dr. Bush (who was attending her sick baby) had several times reduced it, and to keep it up had applied strips of adhesive plaster; this caused pain from pressure upon the eyelid and eye-bulb. It was removed, and a flannel pressure bandage applied, which gently raised the right cheek. This could not be borne either. The swelling and congestion of the contents and surroundings of the orbit increased. Shortly afterwards the occurrence of thrombosis of perceptible and palpable enlarged orbital veins was suspected, and soon established. Nursing of her baby was stopped about June 1, 1881. She improved somewhat in general health for three weeks afterwards; then enlargement of the orbital contents and surroundings again manifested itself, and the eye, which had been totally lost from sloughing of the cornea and plastic iridochroiditis, and was very painful, was removed under anæsthesia. The orbit seemed to be filled with a mass of veins, feeling like a varicole, very thinly covered. The night after the operation her menses came on, and next morning she had intense pain in right orbit and right side of head. Second attack of thrombosis ensued. She manifested serious and threatening symptoms of purulent infection for some weeks; but then improved. In July her menses again appeared, and a third attack of thrombosis of a slight character accompanied it. She soon recovered from it. For some months thereafter slight swelling of the orbital contents occurred at each menstrual period. By the end of the year this ceased. In April, 1882, the everted, dependent, and enlarged lower lid was reposited and kept up by strips of adhesive plaster. She has lately reported parts about orbit get smaller at menstrual epochs. She has entirely recovered.

DR. WILLIAM F. NORRIS, of Philadelphia, presented a paper entitled

HEREDITARY ATROPHY OF THE OPTIC NERVES,

which, in his absence, was read by Dr. Harlan.

The first patient, æt 49, well developed, had complained of losing sight during the past year, and had now become so blind that he had difficulty in getting about without assistance. A cloud settled over his vision so that he could not see signals, being employed on a railroad. At present his eyes appear normal externally, the pupils of medium size, and respond to light. Central vision almost completely abolished in both eyes. Complains of bright light. Disk of the right eye slightly ovoid vertically, with choroid ring, slight central excavation, but the rest of the disk of a greenish-gray hue—entirely devoid of capillarity, but central vessels of about usual calibre. Choroid perhaps more granular than usual; very slight retinal haze. Disk of left eye more nearly round, remains of choroidal ring, scleral ring too marked, outward a black speckled patch one and a half times the width of main retinal veins.

Treatment, $\frac{1}{32}$ grain of strychnia three times daily, gradually increased to $\frac{1}{16}$ grain; result being improvement of vision, enabling the patient to walk about with much more safety. Strychnia treatment continued some time longer, but without apparent further benefit.

A first cousin of this patient was similarly troubled, and under the same treatment the central cloud diminished, and peripheral vision was markedly improved. The ophthalmoscope had revealed greenish atrophy of optic nerves, with entire want of capillarity of disk; little change in calibre of central vessels.

Here was an illustration of hereditary atrophy, beginning with the maternal great-grandfather, and extending through five generations. One uncle, after becoming blind, recovered his sight sufficiently to resume his ordinary occupation.

In both these cases, and those of pigment degeneration of the retina, heredity is frequently observed, but in the one the affection always starts after puberty, with neuritic atrophy of the optic nerve, and cuts off the central vision, while peripheral vision remains comparatively unimpaired. The other, also hereditary, localizes itself in the periphery of the retina, often early in life, producing a secondary atrophy of the optic nerve, leaving central vision intact often for many years.

He believed that in these, as in almost all other atrophies, a certain degree of improvement in the peripheral vision is to be obtained by the persistent use of strychnia, and that it is due not to any specific action on the nervous system, but to the fact that it so increases arterial pressure as to drive a greater supply of blood into the shrunken capillary vessels of the optic nerve and retina, and thus restores proper nutriment.

THE PRESIDENT, DRS. HARLAN, KIPP, and LITTLE, referred to instances of retinitis pigmentosa extending through several generations of the family.

DR. W. S. LITTLE, of Philadelphia, read a paper on

THE INFLUENCE OF THE FARADAIC CURRENT IN THE TREATMENT OF VITREOUS OPACITIES, WITH CASES.

The improvement found on diminishing the size of a vitreous opacity in a case of retinitis pigmentosa, which was being treated by the interrupted current with appropriate internal treatment, syphilis of a hereditary type existing, had led him to use it in all opacities of the vitreous, in addition to accepted methods of medication. He used it in 1877, but had recently used it in a larger number of cases.

Henri Curnur, in 1874, used the constant current in eight cases of vitreous opacity, with rapid improvement. Dor used both constant and interrupted in 1872 for change in choroid and retina.

The method of applying is either through one hand and upon the eye, or from nape of neck and upon the eye. A weak current and for a few moments, increasing time and strength at each application every other day till result is obtained. Satisfactory result is obtained in one, two, or three weeks, according to the amount of change in vitreous.

DR. C. S. MERRILL, of Albany, reported

A CASE OF GLIOMA OF THE RETINA IN A PATIENT TWENTY-ONE YEARS OF AGE.

The patient presented himself at the Albany Hospital, in November, 1878; was twenty-one years of age; had always enjoyed good health. There was complete detachment of the retina, which hung in folds and presented the characteristic appearances of glioma of the retina. The eye was removed; a portion of the fresh retina examined microscopically showed the growth to be simple glioma. The examination of the hardened eye showed the same, also, that the glioma proliferations had *not* extended into the optic nerve. Up to the present time, four years later, he has not had a return of the trouble, though now he is very low with phthisis, which began to devlop about a year ago.

The case is of great interest, inasmuch as it is the

first ever reported of glioma of the retina occurring in a patient at such an advanced age.

Dr. John Green, of St. Louis, read a paper entitled

A CASE OF RUPTURED ZONULA, WITH REMAINING ACCOMMODATION.

Also a second paper, entitled

AN OPERATION FOR ENUCLEATION, WITH REMOVAL OF TARSAL CARTILAGES AND CONJUNCTIVAL SAC.

Three cases, in which this operation had been done, twice by himself, were related. In the first case, the patient being a young farmer, the operation was performed some years ago for epithelioma, involving the tissues of the orbit. Although the eye itself was intact, it had to be enucleated, in order to remove the whole of the diseased structure. The dissection included the whole of the conjunctival sac and the tarsal cartilages, being a removal of the growth from Tenon's capsule. The skin was brought together by two or three sutures, leaving a considerable gap next to the nose to heal by granulation. The greater part of the lachrymal gland doubtless was removed with the tumor, and there was no lachrymation or œdema afterwards. He saw the patient two or three years after the operation. There was a perfectly smooth cutaneous covering of the orbit, and a scarcely visible incomplete linear cicatrix remained, indicating the original line of opening of the lids. The condition was certainly in all respects better than what could have been obtained had any part of the conjunctival sac been left. In the second case, the result of the operation also was satisfactory; likewise in a third case, the operation having been done by Dr. Arlt.

Dr. Green also made some

REMARKS ON OPERATION FOR ENTROPION.

In opening his remarks, he said he accepted the explanation given by Arlt in his hand-book, that most cases of entropion and trichiasis of the upper lid are the result of trachoma. The first stage in the operation which he did to relieve this deformity consisted in making an incision through the conjunctival surface, parallel to the lid margin, and one millimetre from the opening of the Meibomian glands. It extended generally from end to end of the tarsus, separating it from the muscular layer of the orbicularis. The second stage of the operation consisted in lifting and retaining the lid margin upward, which might be done by taking hold of the row of cilia—if they remained, using them as a lever—lifting them up, and sticking them to the front of the lid with collodion, so that, after healing shall have taken place, the cilia are found to occupy their proper position and take proper direction. This simple procedure of availing one's self of the line of cilia is not always sufficient; it is generally advisable also to establish a cicatricial process in the integument, which is done by cutting out a strip of skin quite near to the point of origin of the eyelash. Two millimetres is the maximum breadth desirable to be removed. There is a cut through the conjunctiva and tarsus from within, the excision of a strip of skin from without, and the nutrition of the lid margin is preserved entirely through the muscular layer. Usually, sutures were then passed by the curved needle, drawing up the margin of the lid, and closing the wound made by the excised strip of skin. Formerly these sutures were left in, but on account of the irritation which they caused, he usually removed them very soon, at present retaining the parts in position by collodion. He had employed this method for the most serious cases of this deformity, and with the highest satisfaction. It was far superior to the methods commonly in use, from which wretched deformity often resulted. The number of sutures employed was usually three.

Dr. Richard H. Derby, of New York, read a paper entitled

A CASE OF ANÆSTHESIA OF THE RETINA, WITH CONCENTRIC LIMITATIONS OF THE FIELDS OF VISION; RECOVERY THROUGH INHALATIONS OF NITRITE OF AMYL.

Patient, a girl aged 8 years, nervous, excitable, grown rapidly of late, recently convalesced from severe attack of scarlet fever. On March 30th she complained of pain in and about the eyes, affecting sight. Vision about half of each eye; eyes examined under atropia, vision as before; no improvement with glasses. On each eye fields limited to five degrees in every direction from the point of fixation. Patient treated with small doses of oxide of zinc; directed to wear blue glasses. After two months vision in no way improved, and on June 1st, vision reduced to $\frac{2}{10}$ of each eye; fields limited as before. It now appeared that the optic disks were paler in their outer halves, deprived of their capillary blush. Inhalation of three drops of nitrite of amyl given daily, each inhalation followed by marked flush of face, with no immediate change for the better in vision. On June 3d, vision $\frac{3}{10}$; June 8th, V. each eye $\frac{6}{10}$, with enlargement of visual fields. June 9th, V. $\frac{9}{10}$ nearly; June 10th, V. $\frac{10}{10}$; again enlargement of fields. June 19th, fields of view normal, V. $\frac{10}{10}$.

The interesting point in this case was not the rarity of the affection, for it is not uncommon, but the persistence of it, the evidence of partial atrophy of the nerve, the tendency of the case rather to retrograde under treatment as ordinarily recommended, and its very marked improvement after use of inhalations of nitrite of amyl.

Dr. Harlan spoke of the case of an hysterical girl, who troubled them a great deal at a clinic for a long time on account of excessive photophobia, which they were unable to relieve by a great variety of methods adopted. Examination under ether showed a healthy fundus. At length an assistant suggested a trial of nitrite of amyl, which was consented to, everything else having failed. He gave her inhalations of it in large quantity, three times a day, and soon she returned to the clinic entirely cured. Some time afterward, however, the hyperæsthesia returned, and this time nitrite of amyl failed to do much good.

Dr. Risley had obtained some benefit from using inhalations of nitrite of amyl in photophobia from disease of the cornea in children. The case of a man was referred to who was relieved for a moment, but after suspending the inhalation photophobia would return.

The President had reported a case to the New York Ophthalmological Society of a man who had been blind twenty-four hours when he presented himself at the hospital. The retinal circulation was found to be almost completely suspended. He wished to see what nitrite of amyl would do in hastening a cure. Under the inhalations the face flushed, and in about three minutes normal vision was restored. He also referred to the case of a child who had had a mild attack of scarlet fever, and afterwards suffered from a certain amount of conjunctival trouble and consulted a physician in Chicago, who pronounced the case one of retinitis. The child was brought east, and Dr. Noyes found a typical case of papillitis, choked disk in both eyes, but vision was $\frac{20}{20}$; no limitation of field, no impairment of ocular perception, no albuminuria or kidney trouble, no headache or constitutional disturbance. The case was novel to him. Dr. H. Derby referred to a similar case.

Dr. Risley said he had examined a number of eyes reported as perfectly healthy, with perfect sight, no brain symptoms, yet in several there was the typical appearance of choked disk.

DR. HOWE referred to the case of a lady who had sudden loss of vision in one eye, which after a number of minutes disappeared, and her sight was practically as good as ever, though receiving no treatment. But the exact state of things returned again after some time, and he found the fundus presenting the appearance described by Dr. Derby. He was waiting to see if a cure would be effected in the same manner as before.

AFTERNOON SESSION.

DR. THEOBALD, of Baltimore, presented a description of a case of

CIRCUMSCRIBED ABSORPTION OF THE LENS, APPARENTLY OF TRAUMATIC ORIGIN, WITHOUT THE REMAINDER OF THE LENS BECOMING OPAQUE.

The patient was a female, 30 years old. A small opacity existed in the cornea near its outer margin, and to this a slender tag of iris was adherent. With this eye V. was $\frac{20}{xx}$ (?) and J. No. 1 could be read with ease. After dilation of the pupil, a well-defined crescentic notch was discovered in the outer margin of the lens, just behind the corneal opacity. A layer of opaque lens tissue formed the boundary of the notch, and in close proximity to this there were also a few punctate opacities in the lens. The patient had no knowledge of the eye having been injured. It was thought probable, however, that a penetrating wound, involving the cornea, iris, and lens, had been received in childhood. If such was the case, the arrest of the cataractous process was most singular and difficult of explanation.

DR. THEOBALD also presented an account of

A CASE IN WHICH A FRAGMENT OF GLASS HAD REMAINED IN AN EYE—PROBABLY IN THE CILIARY BODY—FOR TEN YEARS WITHOUT PRODUCING SERIOUS CONSEQUENCES.

The accident was caused by the explosion of a glass test-tube, a minute fragment of glass being driven through the cornea into the anterior chamber, where it was seen hanging by a shred of tissue attached to the corneal wound. This, however, gave way after a few minutes, and the glass fell through the pupil into the posterior chamber and disappeared. Marked inflammatory reaction followed, but, under active treatment, subsided in about two weeks, leaving the eye with no trace of the injury but a minute corneal scar. Since then it has remained entirely free from irritation, and has given the patient no inconvenience whatever; and up to the present time—now ten years after the accident—its vision remains normal for both near and distant objects.

DR. GREEN recalled a case which he saw in consultation, in which a piece of percussion cap had lodged in the lens without producing general opacity, the period of tolerance having covered a good many months.

DR. POOLEY had seen a case in which a triangular piece of glass, about three millimetres in size, lay apparently in the iris, midway between the pupil and attached margin of the iris. It had produced no symptoms demanding interference.

DR. KNAPP thought the tolerance of foreign bodies in the eye usually depended more upon their size than upon other conditions. The fear from uncleanliness was often exaggerated. The foreign body to be innocuous must be small, but all small bodies were not innocuous.

THE PRESIDENT mentioned a case in which a piece of iron had passed through the cornea and was adherent to the lens, having remained in this position seventeen years, and a number of physicians had desired to remove it, but fortunately he had not allowed any one to do so yet.

DR. KIPP had under care a practitioner, who, for about eighteen years, had had a piece of percussion cap, probably in the retina, sight remaining good, and no irritation. The case was further discussed by the President, Dr. Knapp, Dr. Kipp, and Dr. Theobald.

DR. G. HAY, of Boston, then read a paper on

A CASE OF EXTENSIVE HEMORRHAGE BETWEEN THE CHOROID AND SCLEROTIC.

The patient was a man who had enjoyed very good health, except for some dyspeptic troubles and some wandering pains, for which his physicians used the word gouty. Dr. Hay saw him on the 21st of May for extensive chemosis, which he supposed would be likely to pass away in a few days. Nine days afterward the chemosis had diminished, the patient was in good spirits; it was supposed he would get well. Two days later he was asked to see him because of soreness about the malar bone, the lower lid slightly swollen, the bulbo-conjunctiva very much injected, the tension about normal; patient saw with that eye but not so well as with the other, Three days later he had pain about the eye in the night; there was more serous chemosis and more injection of the bulbo-conjunctiva; slight discoloration of fluid in anterior chamber; pupil as in healthy eye; vision not so good; patient pale and feeble. A few days later pupil did not respond as well as in other eye. June 10th, under ophthalmoscope, large grayish swelling came into view from above, showing no vessels at that time; and when he looked down a dark mass came into view from below, which was less defined. Upper mass somewhat evenly convex and dark gray. As the case was unusual, he had the patient see Dr. Hasket Derby, another specialist, both of whom considered the case to be one of intra-ocular tumor. Not being able to account for the condition in any other mannr, Dr. Hay enucleated the eye for the supposed tumor on June 13th. On examination it was found that the anterior half of the choroid was separated from the conjunctiva very extensively all round by a layer of blood which in some parts was three-sixteenths of an inch thick, extending between the membranes into the posterior half of the eye where it gradually became less thick.

DR. KNAPP had described exactly a similar case in an article on intra-ocular tumors. It taught us to be cautious in the matter of diagnosis in such cases.

DR. G. C. HARLAN, of Philadelphia, then described *A Test for Simulated Monocular Blindness.*

DR. W. S. LITTLE related a case of *Remains of Hyaloid Artery.*

DR. F. BULLER, of Montreal, read a paper on *A Somewhat Peculiar Case of Alopecia of the Eye-lids.*

THE PRESIDENT, DR. H. D. NOYES, of New York, read a paper on

AIDS IN THE REMOVAL OF FOREIGN BODIES FROM THE CORNEA.

In the first paper he described a convenient method for illuminating the eye and magnifying any foreign body which may have become attached to the cornea, thus facilitating its removal without the aid of an assistant. The two and a half inch magnifying lens and the illuminating lens were respectively attached to a finger of one hand, the fingers on which hand also were used to retain the lids open, while with the other hand the foreign body could be removed. He had found this method exceedingly convenient, especially where no assistant was at hand. The lenses could be carried in the vest pocket.

In this connection he referred to a case of foreign body in the cornea, it not having gone through into the anterior chamber, but projecting a little beyond the inner surface of the cornea and not sufficiently on the outer surface to be removed by the forceps. From

a face view the wound was larger than the foreign body. Considering the usual methods of removal in such cases to be hardly applicable or appropriate, he took a needle of suitable shape, inserted it alongside the foreign body, and succeeded in getting the needle directly behind the body and tilted it out, losing scarcely any of the aqueous humor.

He mentioned the case of a child who, a week before he saw her, received an injury by the falling of a chestnut-burr upon the unclosed eye while looking up into a tree. Half a dozen little points of the burr, which were sticking in the cornea, were removed with a fine pair of forceps.

Dr. Seely referred to a similar case, the patient having fallen upon a weed from which many fine spines projected. He was unable to remove the several pieces upon the cornea with the forceps, but had to make an incision the entire length of each, and lift it out of its bed. The boy has perfect sight, and there is no opacity of the cornea.

Dr. McFarland had extracted a foreign body from the cornea of a patient in the same manner referred to in the President's first case.

Dr. Noyes then read a second paper—

PENETRATION OF A FOREIGN BODY INTO THE ORBIT; PROBABLE WOUND OF THE BRAIN, AND TOTAL AMAUROSIS.

The case was that of a boy who, last April, in playing with a mate, accidentally turned his head in a manner to receive the sharp point of a wooden sword on the lower and outer margin of the orbit, just above the malar bone, the penetrating fragment, six and a half centimetres in length, breaking off at its point of entrance into the orbit. It was extracted by some person in the house. A physician was called who gave a hypnotic. Total blindness in that eye occurred immediately after the injury. Dr. Noyes saw the patient twenty-four hours later. The pupil was partially dilated, and did not respond to light. The optic nerve was intensely red, very slightly swollen; veins turgid. The other eye appeared normal. No constitutional symptoms developed, although it was feared, on account of the length of the foreign body, that the meninges and brain were injured. It was uncertain whether the affection of the optic nerve was due to direct injury by the penetrating object or indirectly to hemorrhage. In this connection he referred to "a case of lodgement of a foreign body in the cavities of the nose, orbit, and cranium, where it remained five months; removal by operation; subsequent trephining for pus in the brain; death, autopsy;" which he published in *The American Journal of the Medical Sciences*, for July, 1882.

July 27th.—Morning Session.

The Society was called to order at 9 A.M. by the President.

The President, Dr. Noyes, read a paper entitled

REDUCTION OF SIZE AND TENSION OF THE EYEBALL BY TOTAL AVULSION OF THE IRIS AND BY NEURECTOMY.

Stimulated by the experiments of Priestly Smith with regard to the causation of glaucoma, he desired to learn whether this author's theories concerning the origin of tension in glaucoma could be substantiated by actual observation. Two cases were related; in the first there being glaucoma of both eyes, total blindness existing in one, and it was the operation and observations upon this eye which related to the matter in hand. The entire iris was removed through a small aperture in the posterior part of the anterior chamber. The lens was of that large size which, according to Smith's theory, might be the cause of the glaucoma. The final result of the operation was a decrease in the tension and relief from pain. The lens, however, projected forward into the anterior chamber, being kept continually in contact with the cornea, which showed greatest tension to exist from behind. In this case, the lens was one of the largest he had seen, being nearly the diameter of the cornea, against which it lay after the operation, and would seem, therefore, to reinforce Smith's theory. The same operation was performed on the second patient, in whom the lens was not of unusual size. The tension, as long as the patient was under observation, which was but a short time, remained as before. No remarkable reaction followed in either case.

The next case related was one in which opticociliary neurectomy was performed on a patient who had hydrophthalmia, the result being a very satisfactory diminution in the size of the eye to nearly normal, without inflammation or a tendency to repeat the process of enlargement.

Dr. Theobald remembered to have seen Mr. Barwell, some years ago, remove the entire iris in a case of glaucoma, in which iridectomy had been of no benefit, and he understood that Mr. Barwell had done it several times, in some cases with benefit.

The President then remembered himself having seen Mr. Barwell do the operation.

The President, Dr. Noyes, then related

THREE CASES OF TUMOR OF THE EYE.

In the first case, a man, fifty-one years of age, received an injury to the eye, after which a small tumor, which had previously existed at the inner canthus, began to enlarge, and reached nearly to the outer canthus, covering over the front of the eyeball, and connected with the upper lid. It was removed. A plastic operation was done. The patient had no further trouble for about four months, when a swelling occurred in front of the ear of the same side. When he presented himself at the institution, this tumor had enlarged considerably. He was very cachectic, evidently having malignant disease. The autopsy showed cancerous nodules in the lungs, brain, on the skull, and various portions of the body. The fact that the disease did not return in the eye on which the operation was done, showed the propriety of not performing enucleation.

The second case was that of a man about seventy years of age, from whom he removed a small growth, about the size of a pea, upon the sclera, between the cornea and outer canthus. Microscopical examination showed that it had all the characteristics of an epithelial growth; but it had not returned, the operation having been performed two years ago.

The third case was one of small-sized intra-ocular tumor, concealed by detachment of the retina. The patient for some time had been under the observation of a specialist, who regarded the case simply as one of detachment of the retina, but an operation, which had to be done to relieve pain, verified the President's diagnosis as above.

Dr. Bullard referred to a case in which he enucleated the eye for a sarcomatous tumor, and afterward applied chloride of zinc paste within the orbit in case some of the remaining tissues might be affected. The patient afterward had symptoms of meningitis, but entirely recovered. An interesting fact was that there should be meningitis without any necrosis of the bones intervening between the eyeball and meninges.

Dr. Prout referred to a case in which he used chloride of zinc to the orbit after enucleation, there being no attempt afterward at granulation, but no bad result occurred.

Dr. Knapp, of New York, read a paper on

METASTATIC CHOROIDITIS.

It was introduced by the report of the case of a young lady who, by exposure during menstruation, con-

tracted a metritis which laid her up for ten days, and was relieved by poulticing. During the attack first one eye inflamed, but recovered in three days. A day after the first eye had become inflamed the other was similarly affected, but got rapidly worse and blind in a few days, from fully developed purulent iridochoroiditis ending in atrophy of the globe.

Dr. Knapp said the great majority of cases of metastatic choroiditis that had come under his notice, resulted from cerebro-spinal meningitis. Blindness occurring in the course of that disease was, however, not always brought about by metastatic choroiditis, but in rare cases by optic-nerve atrophy. He reported a case where one eye had become blind from the latter, the other from the former, affection. He thought that the well-developed cases were incurable, but that there was also a certain number number of milder cases, where the embolic process was limited in extent, that might get well. He laid stress on the prophylactic treatment, care during menstruation and confinement, and as curative measures recommended cold applications to the eye, and quinia internally.

DR. GEORGE C. HARLAN, of Philadelphia, reported a case of

SARCOMA OF THE LACHRYMAL GLAND FORCING THE EYEBALL DOWNWARDS, FORWARDS, AND OUTWARDS.

The patient was a man 70 years of age, in excellent health, and the tumor, which had been growing for four years, had never given the slightest pain. It was as large as a hen's egg, and had completely dislocated the ball, forcing it downwards, forwards, and outwards. The top of the equator was below the level of the pupil of the other eye. Removal was entirely accomplished, as there were no adhesions, and two weeks after the operation the eye had nearly resumed its normal position. Vision, which had only been quantitative, was improving. Microscopical examination showed the growth to be a spindle-celled sarcoma. Neoplasms of the lachrymal gland, particularly of a sarcomatous character, are considered rare. The points of special interest in the case are the entire absence of pain, and the external direction of the dislocated eyeball. An internal direction would be naturally expected, and is frequently included, as is also pain, among the diagnostic symptoms.

DR. KNAPP remarked that he had lately removed a similar large tumor of the lachrymal gland. Primary union took place, and the globe returned to its natural position, normally movable. There was optic neuritis after the operation, now slowly disappearing. The aspect of the cut surface was different from what he had seen in these tumors. It was homogeneous, purplish-red, of the consistency of flesh, no amyloid reaction. Immediate cursory examination with the microscope showed a scant amount of connective tissue fibres with many small round and spindle-shaped cells. No indication of a glandular structure.

DR. HARLAN also exhibited

AN IMPROVED TRIAL GLASS FRAME,

which he thought had some advantages over any now in use; the principal of which are, that it is very light, and that the troublesome spring for holding the glasses is dispensed with. The graduated grooved arc for cylinders is attached to the lower half of a light ring, the tip of which is connected with the horizontal bar by a sliding clamp. There is but one groove, but there are hooks on either side of it for holding glasses, so that three glasses can be used together.

DR. KIPP, of Newark, N. J., read the

HISTORY OF A CASE OF ACUTE INFLAMMATORY GLAUCOMA, WHICH WAS FOLLOWED BY CEREBRO-SPINAL MENINGITIS.

The patient, a German woman, fifty-one years of age, who had previously been in good health, was attacked by severe pain in back and head ten days before, for the relief of which she had, on the advice of her physician, applied fly-blisters to the right forehead and behind the ear. Half an hour after their application, very severe pain in the right eye came on, and has continued since. Eserine was applied by another physician, who sent the case to the reporter for operation. The eye was found to present the usual symptoms of acute glaucoma. An iridectomy was made at once, and gave immediate relief. Three days later, the other eye became glaucomatous, and was treated with eserine, which cured this eye in a few days. Ten days after the iridectomy, the patient was discharged cured; but ten days later, the eye which had been iridectomized, became again inflamed and very painful. The left eye, a few days later, showed many of the symptoms of acute glaucoma, and an iridectomy was also made on this eye. The operation proved, however, of no avail. The pain in the head continued. Distressing nausea came on, and the patient had night sweats and mild delirium at night. The delirium gradually increased in severity. Bilateral convulsions and involuntary evacuations; coma. The patient died ten weeks after first symptoms showed themselves. Leeches were applied to the temples. Quinia, calomel, and iodide of potassium were given at different times. In the opinion of Dr. Kipp, the glaucoma was in this case due to the cerebral disease.

THE PRESIDENT referred to a case in which an attack of acute glaucoma was the initiatory symptom of serious brain phenomena, which terminated in death. There was found softening of the brain, with extensive and very severe atheromatous degeneration of the arteries.

DR. S. B. ST. JOHN, of Hartford, then read a paper on

GLAUCOMA FULMINANS.

In March of this year he was sent for to go into the country to see Mrs. L. He found a woman of 59, well nourished and enjoying general fair health, who said that, about forty hours before his arrival, as she was sewing, she felt as if something had got into her left eye. Nothing could be seen by her friends and she kept on, but the irritation increased. In about two hours a second inspection revealed mydriasis, and the pain was increasing. She suffered terribly through the night, but morphia finally relieved the pain, and she discovered great impairment of sight and sent for him. He found the right eye normal in structure and function, the left with pupil dilated, T + 3, media obscured, and V = hand at 6″. Diagnosed glaucoma, and performed an iridectomy at once. This eye did well, and left eserine with the family physician to be used in case the other eye became affected, which I represented as quite probable. On the fourth day after the beginning of the trouble in the *left*, and the second day after the operation, vision began to fail in the right, and pain to be present, but the pain was at no time as it had been in the fellow eye. Eserine was used at once, and he reached the patient thirty-six hours after to find the right eye the counterpart of the left one when first seen. An iridectomy was at once done, and the progress of the case from that time was satisfactory, the lady reporting two months later with V $\frac{20}{50}$ in one eye, and $\frac{20}{40}$ in the other, having had no pain or other trouble since the operations. The case was reported because of the comparative infrequency of glaucoma fulminans, and because of the short time intervening between the affection of the two eyes.

DR. ST. JOHN also read a paper entitled

REMOVAL OF PARTICLES OF IRON FROM THE LENS BY MEANS OF A MAGNET.

In January last a blacksmith came to him with the

following history: Three months before, while shoeing an ox, he felt something strike his eye, but the irritation soon passed off, and he thought no more about it for two days when the eye became painful, and he went through with what was probably a sharp attack of iritis without treatment other than anodynes. The vision in the eye was reduced to perception of light, but the eye became quiet and remained so till two weeks before coming for advice, when it became painful and the fellow eye sympathized. Dr. St. John found a traumatic cataract with post-synechiæ, and just at the edge of the pupil a brownish spot extending beneath the pupillary edge. In this brownish spot he thought he could see a black speck. The patient was etherized, and a free incision made with a Graefe knife. He then attempted to do an iridectomy to facilitate the escape of the lens substance, but the traction of the forceps upon the adhesions ruptured the capsule, and lens matter welled up into the anterior chamber. Remembering the black spot which he had seen, he passed the point of a Gruenig magnet into the soft lens matter, and upon withdrawing it found a particle of iron adhering, which was too small to be measured, but which was about twice the size of an ordinary period mark in print. The case made a good recovery, so far as the relief of irritation to the eye operated on, and of the sympathetic irritation was concerned, and the vision was decidedly improved.

Dr. Mittendorf, of New York, presented a paper on

EMBOLISM OF THE CENTRAL ARTERY OF THE RETINA.

He reported three cases of this rare disease under observation. The first case, that of a middle-aged lady who had had previous attacks of rheumatism and valvular lesions of the heart, was suddenly blind after violent exercise, which was followed by gradual clearing up of the upper part of the field of vision. In this case the embolism could be distinctly seen in the upper branch of the central artery. The vision improved in course of time to $\frac{22}{100}$, but the field of vision did not improve materially, leaving the lower part of the field obscure.

The second case, that of a literary gentleman, about forty years of age, who had likewise a severe attack of rheumatism several years ago which resulted in valvular lesions of the heart. In this case the disease came on suddenly on going rapidly up-stairs. The seat of the embolus must have been high up in the main artery, for the characteristic appearances of the retina were soon superseded by marked atrophic changes which were especially manifest in the optic disk. There was complete blindness in the beginning, but in the course of a week a collateral circulation, which could be distinctly seen in the shape of two ciliary vessels at the nasal side of the optic disk, restored a portion of the retina to its function, and a small part of the field of vision remained. The vision in this small temporal portion of the field improved gradually up to $\frac{10}{200}$, whilst in the remaining part of the retina no perception of light was seen.

The third was that of a middle-aged German, who had also rheumatism and mitral regurgitation. He was attacked suddenly one evening, on lifting the shutters of his store, with blindness of the left eye. The field of vision in this case cleared up the next day considerably, leaving the nasal part entirely free.

The first two cases remained under observation for nearly a year, and the vision of those eyes remained tolerably good. The treatment in these cases consisted in the administration of digitalis, and later of strychnia and electricity. All these cases present heart lesions with a previous history of rheumatism. In two of the cases the left eye, in one the right eye, was the seat of the embolism. In all of them the onset of the disease was sudden, and was followed by complete blindness in the beginning. The characteristic appearances of the retina were very marked, and the cherry-colored spot which is universally found in these cases remained in the one case for nearly ten months; in the other case it was followed by hemorrhagic effusions into the fovea centralis, and the red spot disappeared with absorption of the effused blood. In all the cases a valuable amount of vision was preserved, which is rather unusual. He depended especially on digitalis as a heart tonic, but was afraid to use nitrite of amyl because it might give rise to a new embolic process. By this treatment in the one case the embolus was apparently forced from the main artery into one of the branches; in the second case the administration of digitalis seemed to improve the collateral circulation very materially. The strychnia and the electricity were employed as nerve tonics for those portions of the retina whose functions were not destroyed.

The following papers were read by title: *A New Method of Oblique Illumination; Premature Delivery to prevent Blindness; A Single Glass for all Distances after Cataract Operations in Young People;* by Dr. E. G. Loring, of New York. *Embolism of the Central Artery of the Retina*, by Dr. W. F. Mittendorf, of New York.

The following were elected

OFFICERS FOR THE ENSUING YEAR:

President, Henry D. Noyes, M.D., of New York.
Vice President, William F. Norris, M.D., of Philadelphia.
Secretary and Treasurer, Richard H. Derby, of New York.

The Society then adjourned, to meet at the Kaaterskill House, Catskill, New York, on the third Wednesday of July, 1883.

CORRESPONDENCE.

LETTER FROM BERLIN.

An interview with Dr. Koch concerning Tuberculosis.

Yesterday I was present during a conversation between one of the assistants at the Pathological Institute and of the assistants (mitarbeiter) at the Gesundheits-Amt. The talk was about syphilis. The worker with germs was bewailing the fact that he had not yet succeeded in isolating the specific cause of syphilis, though he had worked long and earnestly with it, and I know him to be as skilful almost as Koch himself. But during his experiments with brood condylomata, he had isolated a virus which, when injected into the body of a rabbit, produced in the substance and upon the surface of the heart, strange to say, nodular masses which looked like, but are not, gummata. These masses or nodules, larger than a pea, invariably occurred, and the observation had been made hundreds of times.

The conversation was short, and might seem insignificant, but it was a straw which shows whence and whither is the prevailing wind.

"What do you take the nodules for?" inquired the pathologist.

"I find nothing specific in them," was the answer.

"But I mean what is the structure of it?" naturally asked the pathologist.

"I have not looked at its structure."

"What, you have not examined its structure! You do not know if it be a neoplasm?"

"No," was the response of the worker with germs. "Finding nothing specific in it, I was not interested in it any further." (I ought to say here, for the benefit of those not acquainted with microscopic work, that examinations with color tests, for colors, and examination for structure, cannot be made at the same time.)

Blank amazement was upon the face of the pathologist.

"What would you expect to find if you did examine its structure?" he asked.

"Well, probably giant cells, multiple nuclei, the ordinary signs of an inflammation," was the reply.

"And how would you account for them?" asked the pathologist.

"Why, I should regard them as the ordinary effects of a necrosis, produced by the action of germs," was the reply; "nothing more, and nothing less."

And this reminded me of a conversation I had with Koch himself when I first came. I was here fifteen years ago, I said, and I had come there to study pathology, as it was then called—meaning, of course, morbid anatomy. I ventured to say that I thought the field of exploration in this direction was pretty well worked up, and that not much further could be expected from it from a purely practical standpoint; that as a practitioner of medicine I had become dissatisfied with the therapeutic results of studies in morbid anatomy, which, after all, could only show us the effects of disease, and had now come to study etiology, in the hope that better fruit would follow a knowledge of the cause of disease.

To this Koch replied that etiology is like a new mine which is just being explored. One must not, because a vein has been discovered, arrive at once at the conclusion that we may find gold in every direction. "It is very much like mining in California," he continued. "A man comes upon gold, and therefore every one believes that all that is necessary is to put in a pick. There has been, and there will always be, much disappointment in the search after truth in every field."

"But," I ventured to say again, perhaps in self-justification, "one can only judge at first from surface indications, and if he feels that he has worked in barren fields, he will likely turn at last to others."

"Then the good that we are to look for as the results of these investigations will come, for the most part," he said, "through prophylaxis, and not so much through direct cure. I believe myself that too much complication has arisen from studies only in one direction."

"You do not believe much, then," I asked, "in the possibility of discovering a method of reducing the virulence of the tubercle bacillus, and thus, by inducing a mild form of the disease, secure a future immunity?"

"I can speak, of course," he answered to this, "only from what is at present known. I can say nothing as to future possibilities, but I will tell you why I consider such an event improbable. It is because there is no analogy between small-pox and tuberculosis. Small-pox is a disease which confers an immunity by one attack. It is so rare as to be a clinical curiosity for an individual who has once had the disease to have it again. But does not every one know that this is not true of tuberculosis? Is it not rather in the experience of every practitioner that one who has had tuberculosis once does have it again and again, until he finally dies of it? Of course, many cases recover entirely; nevertheless, every practitioner knows that one attack does not give immunity to future attacks. That is one standpoint from which to regard this question, and it is the standpoint of clinical observation. Now we can add to this another substantiating fact. You saw yourself the dog which was injected with a minimum quantity of tubercle bacilli. The injection was made in the abdominal cavity, and it produced an exquisite tubercular peritonitis. Nevertheless, the dog finally recovered entirely, and seemed perfectly well. Then the same dog was used again, and a large quantity or number of the bacilli was introduced into the abdominal cavity. If you will go down to the animal quarters to-day, you will see that the dog is fatally ill. The abdomen is highly tumefied, and death will probably occur to-day or to-morrow. Now, if one attack conferred any immunity to future attacks, it ought to have been impossible to have produced the second attack. Hence I do not now think it possible to prevent the disease in that way, nor do I think it necessary to try it. For individuals affected with the disease can be prevented from disseminating it."

"By destroying the sputum," I interposed.

"Not only the sputum" he said at once, "but every source of contamination. So soon as it is universally recognized that tuberculosis is an acute infectious disease, it will be treated like the other acute infections, by better care of all the persons attacked, by isolation, perhaps, in properly arranged institutions, etc., and by having far more care than ever paid to the meat and milk of tuberculous cows, cows suffering with *perlsucht*, which we now know to be tuberculosis."

"About basilar meningitis," I asked, "would you kindly repeat what you said before?"

"Well, I repeat, that I have always found somewhere a caseous gland, usually among the bronchial glands, often among the mesenteric glands, that could account for the source of the bacilli in the brain without involving the possibility of inhalation directly through the nose. We have here some beautiful specimens" (holding one up), "which show a caseous mass protruding into the calibre of a vessel. From this mass particles might be easily washed off into the general circulation. This microscopic specimen was brought in a few days ago, and I had no difficulty, after tinting it with the proper colors, in showing [putting in under the microscope], as you may now see yourself, the presence of myriads of bacilli."

"The opponents of the germ theory in general," I said, "claim that the germs produce their deleterious effects by chemical action, rather than by direct destruction or consumption of the tissues."

"As to that," he replied, "no one knows as yet how they act. Possibly they may evolve chemical products which do the harm. But that is after all only a side and subordinate question, for if the germs were not there the effects would not follow. It is enough for us now to have discovered the presence of them as the cause of the disease. Thus for instance in trichinosis, it is not probable that the trichinæ kill by their mere presence. It is not improbable that they may evolve some chemical products, and through them indirectly produce the results; but the prime fact remains that, if the trichinæ are not there, the disease does not occur. Some future investigations may show us just exactly how the results are produced. This is a question more of scientific than of practical interest. By the way, will you tell me why, among your people, who are known to be the most practical people in the world, so little care is taken to prevent trichinosis? In the examinations which I have made of American hams, one in ten turns out trichinotic, and other observers here have often found trichinæ in one in fifteen."

I was not aware that the percentage was so enormous as that, I said, and could only reply that cases of trichinosis in my part of the country, that which furnished the most pork for exportation, were so rare as to hardly supply us with enough clinical material for illustration purposes. To this Dr. Koch urged that our people probably do not eat much raw meat.

This, and the fact that the meat used at home and that exported is not the same in character, will probably reconcile the apparently discordant facts.

At this point the conversation was interrupted by the announcement that a party of military physicians had been sent in to witness the demonstrations. Every day the tide of visitors increases, until it is becoming a serious interruption to the regular work. Hereupon, I

asked permission to report the substance of the conversation, assuming myself all responsibility for misconceptions, knowing that there was abundant opportunity for future corrections. With the amiability which is characteristic of men of science the permission was given at once, and I took down my notes on the table before I left.

I have yet to describe the exact methods of preparation of the culture substances, and the details of the color reactions for practical use in recognition of the tubercle trouble in the sputum or in sections; for I feel sure that, whatever progress may have been made at home with practical work, some disappointment and discouragement must have occurred to the apprentice, for want of mention of details which the master-workman takes it for granted are well known.

J. T. W.

Berlin, June 30, 1882.

NEWS ITEMS.

CANADA.

(*From our Special Correspondent.*)

New Medical School.—The Medical Faculty of the new Western University of London, Ont., has been organized, and the prospectus issued for the first session. The Dean is Dr. Charles G. Moore, and the Registrar Dr. John A. Stevenson. Among well-known men connected with the Faculty are Dr. Bucke, Medical Superintendent of the London Insane Asylum, and Mr. William Sanders, ex-President of the American Pharmaceutical Association. There are now ten medical schools in the Dominion, three of which are French and seven English.

American Association for the Advancement of Science.—The meeting this year will be held in Montreal on the 23d of August. Members of the profession who purpose being present are requested to send their names to Dr. Osler, 1351 St. Catherine Street.

Health in Michigan.—Reports to the State Board of Health, for the week ending July 22, 1882, indicate that whooping-cough, remittent fever, and erysipelas increased, and that influenza, puerperal fever, tonsillitis, consumption, measles, inflammation of the bowels, cholera morbus, pneumonia, cholera infantum, and bronchitis, decreased in area of prevalence.

Small-pox was reported present during the week ending July 22, and since, at 10 places, as follows: at Detroit, Flint, Lansing (one case, convalescent), in the township of Burton, at Mt. Morris, and at Hastings, July 22; at Wayne Co. Pest House, at Deerfield, Lapeer Co. (one case), July 23; at Grand Rapids (12 cases), July 24; and at Westwood, ten miles north of Kalkaska, July 27. At Grand Rapids one man had small-pox who had it 16 years ago.

Sanitary inspectors report, for the week ending July 22, 15 cases of measles brought by immigrants arriving at Port Huron, and 6 cases of measles among those arriving at Detroit.

Senator Cameron's Joint Resolution.—At the annual meeting of the Juniata Valley Medical Society, held at Cresson, Cambria County, Pa., July 18, 1882, the following preamble and resolutions, after free and full discussion, were unanimously adopted, viz.:

Whereas, The Hon. J. D. Cameron, one of our Senators in the Congress of the United States for Pennsylvania, has introduced into the Senate a joint resolution, providing that it shall be a misdemeanor, punishable by a fine of five hundred dollars and dismissal from office, for officers of the United States Government—civil, military, or naval—to make discrimination in favor of or against any school of medical practice, or its legal diplomas, or its duly and legally graduated members, in the examination and appointment of candidates to medical service in any of the departments of the Government; therefore,

Resolved, That this Society, representing the medical profession of the entire Juniata Valley and largely that of Central Pennsylvania, regards said joint resolution of Senator Cameron as tending only to degrade and subvert the science and rational practice of medicine, and injure the public service.

Resolved, That a copy of this action be forwarded by the Secretary to Senator Cameron, with a respectful request that he will not further favor or urge the passage of said joint resolution by the Senate.

The Columbus Medical Journal, the first number of which, bearing the date of July, 1882, is just received. It presents the general appearance of the late *Ohio Medical Journal*, of which it seems to be a continuation, having the same editors and publishers. It contains several valuable original papers, has a full table of contents, and the editorial pages are marked by the same sprightliness which characterized its predecessor.

Illness of Dr. Wm. H. Mussey.—We learn with regret that Dr. Wm. H. Mussey, the distinguished Cincinnati surgeon, was stricken with paralysis on Monday afternoon, and at the latest report was not expected to live.

The American Dermatological Association will hold its Sixth Annual Meeting at Newport, R. I., on August 30th and 31st, and September 1st.

Chair of Surgery in the University of Edinburgh.—Mr. John Chiene has just been elected Professor of Surgery in the University of Edinburgh, to succeed the late Prof. Spence.

Mr. F. M. Balfour has been elected Professor of Morphology in the University of Cambridge, England.

Mr. T. Spencer Wells, Surgeon to the Queen's Household, has been elected President of the Royal College of Surgeons of London.

Prof. Vogt has been called to the Surgical Chair in Griefswald, in place of the late Prof. Hueter.

M. Pasteur has received a medal from a committee formed from the members of the Académie des Sciences, Académie de Médicine, Société d'Agriculture, and the Faculté des Sciences, in consideration of his important discoveries in pathology.

Académie de Médicine.—The committee appointed for the purpose, have proposed the following names for the vacancy in the Section of Physics and Chemistry: 1st, and *ex æquo*, MM. Garid and Javal; 2d, M. Bouchardat; 3d, M. Hardy; 4th, M. Onimus.

The Manufacture of Opium.—The *Scientific American* for July 29, 1882, contains an interesting illustrated article on the processes of manufacture of opium.

Koch's Investigations.—The British Association for the Advancement of Medicine by Research has requested Mr. Watson Cheyne to undertake, under the auspices of the Association, the verification of the results lately obtained by Koch on the subject of tuberculosis, and the comparison of these with the results obtained by Toussaint and other observers, and have made a pecuniary grant for the purpose.

LIGATURE OF THE INNOMINATE ARTERY.—The last report of Mr. Thomson's case of ligature of the innominate artery (see THE MEDICAL NEWS, July 15th, p. 82) is to the twenty-seventh day after the operation. The patient continues to do well, temperature normal, pulse 86; the track of the drainage-tube has healed, and only a small superficial sore now remains unhealed. The aneurism is without pulsation, and is becoming smaller.

This case will no doubt revive the oft-discussed question of the justifiability of this operation. Of late years, the general opinion has been against it, and in most of the surgical text-books this view is strongly expressed. It is doubtful how often the operation has been carried out. There are five cases attributed to Dupuytren, Lynch, Pirogoff, Bergelsky, and Peiscotto, which do not rest on sufficient evidence to enable us to include them in our list of cases; in all of these cases the operation, whatever it was, proved fatal. But there are twelve undoubted cases performed respectively by Mott (1818), Graefe (1822), Norman (1824), Arendt (1824), Hall (1830), Bland, Lizars (1837), Hutin (1842), Cooper (1859 and 1860), Gore, and Smyth. Of these, eight cases perished from hemorrhage, one from acute pericarditis, one from inflammation of the sac of the aneurism and pleuro-pneumonia, and one from blood-poisoning. Smyth's case is the only one that recovered, and this only after the patient had experienced four attacks of secondary hemorrhage, and had had his vertebral artery ligated. In many of the fatal cases, although death took place many days after the operation, the aneurisms did not show any evidence of consolidation. We shall be very glad if Mr. Thomson's case prove ultimately successful, as it now promises to do. But although a month has elapsed since the operation, and all looks well, we cannot forget that in two cases—Graefe's and one of Cooper's—death occurred from hemorrhage on the sixty-seventh and forty-first days respectively. Recent surgical advances have altered the position of this operation to some extent, for they have provided us with several materials which, while successful in leading to the permanent occlusion of the artery, do not cause suppuration of its coats. This removes one great source of danger. But the deep position of the artery, its shortness and its relations to other important structures, render the procedure a very difficult one. There are at least four cases reported where the surgeon has been unable to complete the operation.

Since the above was written, Mr. Thomson has forwarded the following particulars of the progress of his case: "My case has now reached its thirty-fourth day. On the thirtieth day there was some bleeding through the sinus, which re-opened. Bleeding stopped spontaneously, and has not recurred. Patient has still normal temperature—in morning, pulse 88. Tumor perfectly still and much reduced in size. Some pulsation apparent in region of the ligatured vessel. No carotid, temporal, or radial pulse." "Violent hemorrhage took place on the thirty-ninth day. It was controlled by shot-bags, and has not recurred since—that is, for sixty hours. There was an interval of nine days between the first and second bleedings. The patient, on July 16, declared that he had never felt better, but I expect a fatal result. He has now survived forty-one days." —*Lancet*, July 15 and 22, 1882.

RUSSIAN MEDICAL CONGRESS.—A Russian Medical Congress will shortly be held at Moscow, after the opening of the exhibition at that city. Among the chief subjects of discussion will be papers on the recent epidemic of diphtheria in Russia, and the mutual relations of State Medical Legislation and Local Sanitary Laws.

NEPHRECTOMY.—On July 12th Mr. Christopher Heath excised the kidney in a young child. The organ was the seat of a rapidly developing sarcomatous growth. The operation was completed without much loss of blood, and the condition of the child was hopeful until the following morning; it then somewhat rapidly sank, and died eighteen hours after the operation.—*Brit. Med. Journ.*, July 15, 1882.

DIED, on July 6th, 1882, in Heidelberg, PROF. NIKOLAUS FRIEDREICH, in the 57th year of his age.

Prof. Friedreich had been suffering for several years from an aneurism of the aorta, which proved fatal by rupturing into the pleura. His principal works were the articles on diseases of the heart in Virchow's Handbook, on diseases of the larynx and nose, a work on progressive muscular atrophy, and the paper on disease of the pancreas in Ziemssen's Pathology, and a large number of other valuable pathological papers. Prof. Friedreich was born in Würzburg in 1825, studied medicine, and was appointed privat docent of pathology in that university. After Virchow was called to Berlin, Friedreich succeeded him as extraordinary professor, a position which he held until 1858, when he was called as ordinary professor of special pathology to Heidelberg, where he was also Director of the Medical Clinic, and founder of the Psychiatric Clinic.

—— On July 9th, DR. ANDREW BUCHANAN, late Professor of Physiology in Glasgow University, at the advanced age of eighty-four. He is best known as one of the first who indicated the true nature of coagulation of the blood.

NOTES AND QUERIES.

"A CANULATED NEEDLE."

To the Editor of THE MEDICAL NEWS.

Sir: In your issue of the 15th inst., I notice "a canulated needle" of Dr. George McClellan's, which is a counterpart of my "tenaculum needle," described in the New York *Medical Record*, Oct. 13, 1877. This needle was placed by me in hands of the Messrs. Tiemann in 1876, and perfected and manufactured by them in 1877, and it not only fulfils all the indications of Dr. McClellan's instrument, but has, in addition to a tenaculum and suture needle, a straight or slightly curved needle and a wire-twister attached.

Yours respectfully,
C. J. CLEBORNE, M.D.,
Medical Inspector, U. S. N.

NAVAL HOSPITAL, PORTSMOUTH, N. H.,
July 24, 1882.

[WE are in receipt of numerous letters of the above tenor, in reply to all of which we may say that it is only claimed for the needle described in our issue of July 15th, that it is a convenient adaptation of an instrument which is well known to be old in principle.]

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT, U. S. ARMY, FROM JULY 25 TO JULY 31, 1882.

RAYMOND, H. J., *First Lieutenant and Assistant Surgeon.*—To proceed at once, with necessary attendants, from Whipple Barracks, *via* Fort Verde, to the scene of recent engagements with hostile Indians, near General's Spring, and bring in those wounded to Fort Verde, and remain in charge of post hospital there until further orders.—*S. O. 112, Department of Arizona, July 19, 1882.*

THE MEDICAL NEWS *will be pleased to receive early intelligence of local events of general medical interest, or which it is desirable to bring to the notice of the profession.*

Local papers containing reports or news items should be marked.

Letters, whether written for publication or private information, must be authenticated by the names and addresses of their writers—of course not necessarily for publication.

All communications relating to the editorial department of the NEWS *should be addressed to No. 1004 Walnut Street, Philadelphia.*

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. XLI. SATURDAY, AUGUST 12, 1882. NO. 7.

ORIGINAL LECTURES.

ON THE USE OF CERTAIN INSTRUMENTS IN THE TREATMENT OF SKIN DISEASES.

A Clinical Lecture,

BY GEORGE HENRY FOX, M.D.,

CLINICAL PROFESSOR OF DISEASES OF THE SKIN IN THE COLLEGE OF PHYSICIANS AND SURGEONS, NEW YORK.

(*Specially reported for* THE MEDICAL NEWS.)

GENTLEMEN: The treatment of skin diseases was formerly considered to lie within the domain of surgery, and external measures were chiefly relied upon for their cure. It is only within recent years that the internal origin of many skin diseases has become thoroughly appreciated, and to-day dermatology is justly considered to be simply a branch of general medicine. There are certain diseases, however, which require surgical treatment, and to these and a few simple instruments which are commonly employed by dermatologists I will invite your attention to-day. Of cancer in its various forms, and other malignant affections involving the skin and requiring removal with the knife, I will not speak, since these naturally come under the notice of the surgeon. There are certain special instruments, however, which are solely used in the treatment of skin affections which it may be well for you to possess, and which, I hope, you will have frequent occasion to use.

The first and simplest of these is a short silver tube, with a calibre about the size of a fine knitting needle, which I term the comedo-presser or extractor. The end of this should be carefully rounded so that it will not scratch or otherwise injure the skin. In many cases of comedo, whether occurring alone or associated with acne, this little instrument will be found to be almost indispensable. You know it is a very common custom for patients suffering from acne to press out the little black-heads, as they are termed, either by means of the thumb-nail or an ordinary watch-key. The watch-key commonly answers the purpose; but, as the hole is square instead of round, and the end is often rough, delicate skins are not infrequently caused to suffer from its use. A number of small instruments have been suggested as substitutes for the watch-key, but a silver tube I have found to be of the greatest value.

We have before us a young woman with pustular acne. Interspersed among the small papules and pustules are numerous projecting black specks which you will recognize as comedos or comedones. As inflammation of the sebaceous glands, which is the essence of acne, is very apt to be excited by the presence of this inspissated sebum in the ducts of the glands, one of the first steps in the treatment of this case will be to remove these fatty plugs; by carefully applying the end of the tube over the black dot and giving it a quick, sharp pressure, the comedo is expressed from the duct with the greatest of ease and commonly with no pain. It is not a pleasant operation, to be sure, and you will find some patients who will wince under this treatment. When the comedos are very dry and hard, it may be found advisable to have the patient steam the face before using the instrument. This can easily be done by placing the patient's face over a vessel of boiling water for a few minutes, the head being covered by a towel. There is always a tendency for the ducts to refill after their evacuation; but if the skin is stimulated by the daily use of soap, the glands will soon resume their natural action. You will notice that the use of this instrument produces a small red spot wherever it has been applied, showing that the skin is in an irritable condition. In some cases you will find the skin so irritable that this simple operation of pressing out the comedo will produce a small whitish lump or wheal similar to that which follows the bite of a mosquito. Where this irritability of the skin exists in a case of acne, you may depend upon it that there is dyspepsia or some underlying condition which aggravates the acne, and it will be impossible to effect a cure without resorting to internal treatment.

This patient tells us that the pustules occur in successive crops, and that they are specially apt to appear during the week preceding her menstruation. Most of the pustules run a rapid course and disappear in a few days or in a week's time. Occasionally deep-seated pustules are formed which do not tend to spontaneous evacuation, but produce subcutaneous nodules which remain for several weeks, or even longer. These give rise to a little pain at first, but soon form firm, painless tumors. The patient is often tempted to prick these large pustules with a needle, which, however, has no beneficial effect. To secure their speedy removal it is necessary to treat them as small dermic abscesses and to open them freely.

The next instrument to which I call your attention is one which is adapted to this purpose. It is, you see, a small spear-shaped lancet, with a shoulder upon either side, which presents the point from going too far into the subcutaneous tissue. If with this instrument we merely puncture the true skin, a drop or two of blood is caused to flow and the lump remains. If, however, we press it into the nodule until the shoulder reaches the surface of the skin, we generally succeed in evacuating a little pus or a small amount of cheesy matter. The wound will heal quickly under these circumstances, and the indurated nodule will be found to have disappeared. In the treatment of all cases of acne indurata a more rapid improvement can be obtained by the use of this acne lance than by any other method of treatment.

The next instrument which I show you is a small kidney-shaped knife or lancet which is used for the purpose of scarification. This instrument varies in its form, and some prefer to use a multiple scarificator, consisting of ten or twelve knives placed side by side, about a millimetre apart. A single blade, however, I think, will usually answer the purpose of scarification; and after a little experience, the parallel cuts may be made very close to each other. This instrument has been recommended for use in a number of skin affections; but the one in which I have found it most serviceable is the tubercular or ulcerated form of lupus, especially when this affects the nose or a part in which loss of tissue is extremely undesirable. The parallel incisions create an amount of inflammation which tends to destroy the morbid cells, and to leave the healthy tissue unimpaired, which would not be the case were a caustic employed for this purpose. In a case of lupus of the cheek, the dermal curette, of which I shall presently speak, or any form of caustic, can usually be employed to advantage, and a smooth scar obtained; but when lupus affects the wings of the nose, as it is very prone to do, our object should not be simply to

destroy the morbid growth, but to do this with the least possible destruction of the healthy tissue. In such a case the results of scarification have proved astonishing, and a nose which seemed almost certain to be wholly or in part destroyed, has healed with a very slight amount of deformity. To use this instrument properly, requires a steady and skilful hand and a certain amount of experience. The parallel incisions should be made as close to each other as possible. The hemorrhage which results can be readily checked by the use of absorbent cotton or a small piece of blotting paper. The cuts heal in a few days, when scarification may be again practised, the incisions this time being transverse to those first made. In a bad case of ulcerated lupus of the nose, this treatment should be repeated once or twice a week for several months. Under this plan of treatment, the ulceration will assume a healthy character, and heal. The morbid growth will gradually disappear, and the final result, though not quickly attained, will prove most satisfactory to both physician and patient. In certain cases of rosacea, scarification may be also employed with advantage. The parallel incisions will usually destroy the fine superficial vessels. Where the nose is considerably enlarged, however, and the cutaneous vessels are very much dilated, the treatment by scarification will generally prove of little service as compared with other methods.

Some of you may be aware that, a few years ago, an English surgeon advocated the use of linear scarification for the removal of superficial vascular nævus or wine-mark. This plan of treatment, however, apparently failed in the hands of all who tried it, save its originator, and has now been generally abandoned. I shall presently speak of a plan of treatment which, in my experience, bids fair to be the only successful method of dealing with this common and disfiguring affection.

Now, let me call your attention to one of the most useful instruments in the surgical treatment of lupus and epithelioma, and one which has been recommended in the treatment of acne, sycosis, psoriasis, and other skin affections. This instrument is the dermal curette—the sharp spoon of the Germans. As you see, it is a small, stout, spoon-shaped instrument, perforated by a circular hole, and resembling the bone-scraper used by surgeons. The instrument may vary a great deal in size and shape, but its purpose is to gouge or dig out of the skin certain morbid growths which are found to be much softer than the normal tissues, however dense or indurated they may feel to the touch of the finger.

The cases of lupus and epithelioma which were formerly allowed to increase in size under inefficient modes of treatment, or submitted to the surgeon for complete excision by means of the knife, are now commonly removed by the use of this instrument.

Our next patient has, as you will perceive, even at a distance, a flattened growth upon the forehead, with a depressed, slightly ulcerated centre, and an elevated waxy margin. This is a case of superficial epithelioma, or rodent ulcer, as it is commonly termed in England. It began six years ago as a small excrescence like a wart. It bled when scratched, and has steadily but slowly increased in size. It is painless, and in its present location would not prove serious if allowed to remain for several years more. At the same time, the patient is desirous of having it removed, and the sooner a growth of this kind is destroyed, the less disfiguring will be the resulting cicatrix. The first and principal point of treatment is to destroy thoroughly the morbid growth. This can be accomplished equally well by the knife, the curette, or by caustics of various kinds. Its removal by the curette is the simplest, quickest, and least painful method which we can adopt. A second point of treatment is to remove all the growth with the least possible destruction of healthy skin. With the curette this can easily be accomplished. Although it feels indurated and harder than the surrounding skin, we will find that this outgrowth will yield readily to the scraping which we are about to employ, while, on the other hand, it would be an extremely difficult matter to dig into the healthy fibrous corium by means of this comparatively dull instrument. The operation is not attended by much pain, and I am sure the patient can stand it without the use of an anæsthetic. You now see how readily the indurated mass can be scraped away, how slight the hemorrhage is, and how quickly we have succeeded in converting the seat of the growth into a patch of raw skin. It is possible now that we have not entirely destroyed all of the diseased cells. To make certain that there shall be no return of the growth, it will be advisable either to cauterize the raw surface, which would give the patient quite as much or more pain than the scraping, or to apply iodoform and tightly bind it upon the raw surface. The application of iodoform, which has been lately recommended in the treatment of lupus, is painless and extremely efficacious in destroying any morbid cells which may remain. It promotes a rapid cicatrization on the ulceration. We will powder the surface thickly with iodoform, cover this with a layer of absorbent cotton, and hold this tightly in place by painting it over several times with flexible collodion. Beneath this dressing the ulcer will probably heal in a fortnight, and possibly without suppuration. The tubercular patches of lupus vulgaris may be successfully treated in a similar way. In Germany, the use of the curette is recommended for the treatment of acne, and I have used it successfully in one or two cases of pustular acne of unusual severity, scraping the pustules and papules relentlessly at intervals of from three to five or eight days. It is only in the severest form of acne that such a harsh plan of treatment, however, would be advisable. To treat the ordinary cases of acne which will come to you in private practice by means of the dermal curette would prove to be the quickest possible means of reducing the number of your patients.

Another important instrument for dermatological purposes, and the last one of which I shall speak, is the electrolytic needle. The use of this implies the possession of a galvanic battery, an instrument which you will doubtless have on hand for other purposes, and the number of affections in which it can be advantageously used is constantly increasing. One of the most important recent advances in dermatology is the operation for the removal of superfluous hair, the development of which reflects no little credit on American dermatology. Until recently ladies afflicted with an unwelcome growth of hair upon the face have sought relief in vain. You may now assure all such who may apply to you for advice that the growth can be readily removed.

I will now bring before you a patient with a few stiff hairs growing from a small mole upon her chin. By destroying them I will best demonstrate the method by which a moustache or beard can be permanently removed. Connected with the negative cord of a battery I have attached a fine flexible steel needle, which I carefully insert into the follicle by the side of oneof these stiff hairs. Grasping the hair with the forceps held in the left hand, I will now ask my assistant to complete the circuit by applying the sponged-tipped positive electrode to the patient's cheek. Electrolytic action is now manifested around the needle by the blanching of the tissue and slight frothing, which those of you who are near will readily observe. I now make gentle traction

upon the hair, which, after the lapse of a few seconds, readily comes away, showing that the hair papilla or matrix of the hair, if I may use the expression, has been destroyed. Pulling out the hairs, or removing them by means of depilatories, is simply a palliative measure. The procedure which you have now witnessed is followed by the complete and permanent absence of hair. The ordinary cambric needles will answer the purpose, although they are more likely to leave a slight pit than the fine needle which I have employed. This operation is a tedious one, and often quite as tiring to the operator as to the patient. The hairs must be destroyed one at a time, and where there are thousands to be removed, as has been the case in several patients on whom I have operated, a considerable amount of time and patience is requisite. To my friend, Dr. Hardaway, of St. Louis, is due the credit of introducing this operation into dermatological practice.

I have already spoken of the treatment of wine-mark by scarification, and called your attention to the disappointment caused by its lack of success in my hands as in many others. I have recently employed electrolysis in the treatment of one or two cases, and succeeded in transforming a dark, unsightly purplish patch into a light pink and far less disfiguring mark. I am not yet prepared to state that wine-mark can be treated by electrolysis with a degree of success equal to that which has attended its use in the destruction of hair, but by the production of numerous minute cicatrices it is easy to improve greatly the appearance of a wine-mark and by further experimentation with this method I trust that the complete removal of such a mark will eventually be achieved.

Having demonstrated to you the methods by which superfluous hair may be removed from the face, an operation which is now thoroughly established, and explained to you the somewhat similar method of treating the superficial vascular nævus, an operation which is comparatively new, it remains for me to speak briefly of the value of the electrolytic needle in the removal of certain facial blemishes of lesser importance.

Telangiectasis.—We will begin with that dilated condition of the capillary vessels which is known as telangiectasis. This affection presents itself in a variety of forms; the most common is that which is seen upon the wings of the nose, either alone or in connection with rosacea. The dilated vessels may be of a bright red hue, or they may appear purplish and tortuous, as in the swollen nose of the drunkard. In either case they are unsightly and call for local treatment. Heretofore this has consisted in slitting up the vessel and applying nitrate of silver or perchloride of iron. More recently multiple puncture or scarification has been employed, but by far the simplest and most effective method of treatment is that recommended by Dr. Hardaway, viz., the use of the electrolytic needle. With a fine and sharp needle, connected with the negative pole of the battery, the dilated vessel is pricked at the point where it appears to emerge from the corium and make its appearance upon the surface of the skin. The circuit being now completed by touching the sponge-tipped positive electrode to the cheek, hand, or any portion of the body, the characteristic blanching is quickly observed around the needle, and in a few seconds the vessel has become white for a short distance from the needle. The object of the operation is to excite enough inflammation at a given point to cut and ligate the vessels as it were, and the number of seconds required to accomplish this end will depend upon the strength of the current, and the distance between the electrodes. Here is a well-marked case of rosacea in a man who is evidently not an advocate of total abstinence—in practice, at least. You see the swollen and tortuous venules upon the sides of the nose, slightly elevated above the level of the skin. In this case we will use twelve cells of a zinc-carbon battery, and apply the sponge to the patient's cheek. You now see the chemical action taking place in the tissue around the needle, and those of you who are near enough can see the bubbles of hydrogen coursing through the vessel and its branches, like the blood corpuscles seen beneath the microscope in the web of a frog's foot. To destroy all of these vessels upon the side of the nose, it is necessary to introduce the needle repeatedly, and allow it to remain each time from five to ten seconds.

In this next patient, a young woman who has come to the clinic on account of another skin affection, you notice upon the cheek a small, bright-red point from which a few fine tortuous vessels radiate. Its spider-like form has given to this affection the name of *nævus araneus*. The patient states that the spot made its appearance a few years ago without any known cause. Very likely it resulted from the prick of a pin or some other trifling injury. It manifests no tendency to increase in size and gives the patient no annoyance, but still she is willing and even anxious to have it removed, if this can be done without much pain. I now insert the point of the needle in the centre of the red spot, which naturally occasions a slight pricking sensation. The patient will now grasp the moistened sponge connected with the positive cord of the battery, and she now undoubtedly experiences a sharp stinging sensation, which is by no means agreeable, although it is not particularly painful. You see that the redness has already disappeared, and in about a minute or two, having now removed the needle, a slight swelling will take place similar to that which usually follows a mosquito bite upon a delicate skin. The result will be a destruction of the bloodvessels and a fine punctate cicatrix, which will be unobservable except upon the closest inspection.

Angioma.—In one or two patients who have been partially stripped in the clinic, I have called your attention to the existence of numerous little vascular tumors of the size of a pinhead or lentil, and projecting slightly above the surface of the skin. These small angiomata are of no consequence when situated upon the body, but when, as occasionally happens, they occur upon the face, it is a very easy matter to destroy them by this simple operation.

When they are as large as a small pea it is advisable to introduce two needles, one connected with either cord of the battery, and have their points almost touch. Angiomata of larger size (the vascular nævus described in works on surgery) can usually be successfully treated by introducing two or more gold-plated needles of larger size. A preferable plan of treatment for these vascular growths, however, and one which I hope soon to have the opportunity of demonstrating is the application of the ethylate of sodium.

Nævus Pigmentosus—Let me call your attention now to another trifling affection of the skin, which is so common that it may be found upon the skin of a large minority, if not the majority, of healthy persons. I refer to the little pigmented spots which like permanent freckles are so often found upon the face, the backs of the hands, and upon covered portions of the body. They are either congenital or develop in early life, and in persons of a dark complexion they may be very numerous. Usually they are not much larger than a pin's head. I will pass around the photograph of a man who had an unusual number of these small pigmentary nævi upon his arms and body. I remember this patient telling me that, although the spots never disappeared, they were much darker in summer than in winter, even upon the covered portions of the body.

Such spots when not elevated above the surface of the skin occasion no annoyance whatever, except when they happen to occur upon a ladies' face. Treatment now becomes an important matter, and again electrolysis comes in play. It is not necessary to insert the needle into the deeper portion of the skin, for you will remember that the pigmentary deposit is situated in the cells of the epidermis just above the papillary layer of the true skin. All that is necessary is to produce a small blister upon the surface of the black spot, and by touching it repeatedly with the point of the needle, we can accomplish this end as readily as by the application of a caustic, and with less likelihood of leaving a noticeable scar. For pigmentary nævi of large size, I will not recommend the electrolytic needle, as I have had no experience in its use in such cases.

Fibroma Simplex.—Upon the cheek of our next patient, a woman of forty-five, you see a little excrescence of the size of a small pea. Such a growth is commonly spoken of as a "wart" or a "mole." Frequently it is pigmented, and the seat of a few stiff hairs, and is called *nævus verrucosus.* The growth in this case is of firm consistence, with a smooth surface and slightly redder than the surrounding skin. It is simply a hypertrophic growth of the fibrous tissue of the corium, and constitutes a blemish which is very frequently seen upon the face of persons of middle and advanced age. Its removal is by no means imperative, and the fear expressed by our patient that it is likely "to turn into a cancer" is unfounded. There are ladies who affect to regard an unsightly excrescence of this kind as "a thing of beauty," but you will find that when they learn that it can be removed with very little pain, and without the use of a knife, they will be very willing to part with it. In this case we will use fifteen cells of our constant current battery, and transfix the growth with the needle upon a level with the surrounding skin. You now see that the growth is turning white from the action of the current, and that the needle can be moved forward and backward with perfect ease. We will now transfix the growth again, the needle being at right angles to its former direction, and allow the electrolytic action to proceed as before for about ten seconds. What will be the result? For about twenty-four hours the growth will be slightly swollen and inflamed, and although it is not necessary, it may be advisable for the patient to keep a hot fomentation over the part. In a few days the growth will shrivel away, possibly forming a minute crust or slough, and in a few weeks there will be nothing but a slight cicatrix to denote the site of the operation.

In the cases of multiple fibromata which occur upon the body and extremities, the tumors are usually too large for this treatment, and they should be removed, if it is deemed necessary, by the knife or galvanocautery.

Xanthoma.—Another facial blemish, which you may be called upon to treat, is the affection which is known as xanthoma or xanthelasma. This appears usually in the form of oval yellow patches upon the upper eyelids near the inner canthus of the eye. One or both upper lids may be affected, and in some cases fainter yellowish patches are noticed beneath the eye. Patients affected with xanthoma are apt to have hepatic derangement, and to present a sallow complexion with dark rings around the eyes. The principal, if not the only, treatment which has been employed in these cases is excision, a remedy which, in the estimation of many patients, is worse than the disease. In the case of a lady who recently applied to me for treatment of xanthoma and, and who was averse to any cutting procedure, I resorted to the use of the electrolytic needle and succeeded in removing the growth. I will not presume to recommend this plan of treatment on the strength of my limited experience, but I shall certainly adopt it in the next case with which I have to deal.

There are some other cutaneous affections in which the electrolytic needle might be employed to advantage, but what I have already said will give you an idea of its value and extended application. It acts like a caustic in destroying the cutaneous tissue, but is more efficient in many respects and under our control to a far greater degree than any ordinary caustic which could be used. It is not a true caustic in an etymological sense, for it destroys tissue by chemical action, and not by the generation of heat as in the platinum wire connected with a galvano-caustic battery. And now, before closing, let me say a few words in answer to questions which might otherwise be asked respecting the character of the battery employed for the purpose of electrolysis, and the number of cells which it is necessary to use. It seems almost superfluous to say that the battery should be of the kind which is known as the galvanic or constant current battery, and yet I have known physicians to attempt the use of electrolysis with a faradaic battery, *i. e.*, one with an interrupted current, which is wholly unsuited to the purpose. The galvano-caustic battery, though producing a constant current, is constructed for the sole purpose of heating a platinum wire, and is equally unsuited for electrolysis. There are a variety of galvanic batteries with different elements, any one of which will answer the purpose of electrolysis, but the ordinary zinc-carbon battery is the one commonly employed. I have used here in the clinic a chloride of silver battery with cells hermetically sealed, and which is therefore adapted to being carried about. It can be tipped over without any danger of ruining a carpet by spilling the contained fluid, but it is an expensive battery, and one very liable to get out of order, and hence not to be recommended for general use. The battery which has given me the most satisfaction is the zinc-carbon battery, manufactured by the Electro-Medical Manufacturing Company, of this city. It possesses electromotive force in a high degree, is very simple in construction, not liable to get out of order, and easily repaired when this becomes necessary. It is constructed with a varying number of cells, but the twenty-cell battery is the size which I should recommeud for use in the treatment of the affections of which I have spoken. This battery is so constructed that if a few of the cells are exhausted the remaining ones can still be used. In the operations to which I have referred, from ten to fifteen cells may be required. If the battery fluid is fresh, the sponge in connection with the positive electrode well moistened, and applied to the skin as near as possible to the needle, the current will be at its maximum strength, and a smaller number of cells required than when the battery fluid is weakened by use, the sponge dry, or nearly so, or when the circuit is completed, by placing the positive electrode in the patients hand—and the resistance to the current thereby increased. These points being borne in mind, a sufficient number of cells should be employed to produce the desired effect, viz: a gradual dissolution of the cutaneous tissue at the point where the needle is inserted. It is always advisable to introduce the needle before completing the circuit, and to break the circuit before withdrawing the needle. By observing this rule an unpleasant shock may be avoided.

TWO CASES OF RUPTURE OF THE MEMBRANA TYMPANI CAUSED BY DIVING.

BY H. AUGUSTUS WILSON, M.D.,

OPHTHALMIC AND AURAL SURGEON TO ST. MARY'S HOSPITAL; PATHOLOGIST TO THE PRESBYTERIAN HOSPITAL OF PHILADELPHIA, ETC.

I HAVE seen two cases resulting from the same cause, and presenting symptoms so different, that I am led to record them; not on account of the rarity of the occurrence, but because I hope the subject will be found to be an interesting one for consideration.

Traumatic rupture of the membrana tympani, caused by diving into water, seems to be a rare accident, judging from statistics. I believe, however, that the reason comparatively so few cases are reported will be found to be either that the rupture was not recognized, or else that the subject was not considered sufficiently important.

In the vast majority of cases the actual lesion is not recognized. The incorrect assurance that there must be water in the ear, and that there is no danger, does much toward tranquillizing the patient, and at the same time preventing his seeking proper and timely attention.

It may be of interest to note that, out of 1652 cases of ear diseases treated in the Eye and Ear Department of the Massachusetts Charitable Eye and Ear Infirmary[1] during 1872, there occurred only three cases of traumatic rupture, but no cases are mentioned as caused by diving. I could as readily quote from the reports of other and similar institutions, but I believe it would be to little advantage, for reasons already mentioned.

CASE I.—Charles K., aged twenty-seven, said that while swimming he dived from a height of about twenty feet, and as he struck the water he heard a very loud noise, which he likened to the firing of a cannon. When he arose to the surface, he found that he heard very indistinctly with his left ear, but his own voice sounded loud and harsh. Testing his acuteness of hearing with a watch that should be heard at fifty inches, I found that he heard it at two inches, while a tuning-fork of low note could be heard very distinctly at ten feet. His perception of high notes was very defective, and his attention was first called to this upon his arrival home, when he found that he could not hear distinctly his mother's voice (a soprano), while his father's (a very deep bass) was quite plainly heard. With each inspiration a loud roar was heard, and it was this annoyance more than anything else that caused him to seek advice.

The diagnostic tube readily confirmed the diagnosis, already made, of perforation, which was found, upon investigation with the otoscope, to be triangular, with the base in the lower anterior quadrant, the apex extending to within a line of the handle of the malleus, and falling inward.

CASE II.—A boy, ten years old, dived from a small boat, and said he thought he must have struck the bottom of the river, for he "heard something crack." Upon coming to the surface, he is represented to have fainted—probably aural vertigo. Upon regaining consciousness, he said he had a "funny feeling" in the right side of his head, and was very dizzy. I saw him about an hour after the accident occurred, and, from his account, was led to examine his head, but found no abrasion, contusion, or depression. He had not noticed any loss of hearing, and was but slightly annoyed by a whistling sound in his right ear when he blew his nose.

I found a curvilinear slit in the upper, and extending into the posterior, portion of the membrane. Hearing, $\frac{18}{60}$. The Eustachian tube was remarkably patulous.

The treatment was the same in each case, and consisted of first thoroughly drying the parts with absorbent cotton; secondly, painting the membrane with collodion. By a little manipulation I was enabled to bring the apex of the triangle, in case I., up even with the rest of the membrane, and securing it there by the adhesive properties of the collodion.

Collodion was resorted to because it was at hand, and I knew it would not exert any deleterious effect upon the tissues with which it would come in contact. The fact that it had been recommended by Critchett in cases of relaxed membrane, suggested its use in these cases. Mucilage of acacia or some similar unirritating substance might be employed for the same purpose. I consider the method of application of greater importance than the material used. With the aural speculum in place, a concentrated reflected light should be thrown upon the membrane, which is then most delicately painted with collodion on a very fine hair pencil. As the collodion dries, the torn portions are brought into place.

I did not see either case for some time, because they thought they were doing well, and needed no further treatment. When I saw Case I., fifteen days after the injury, the wound had entirely healed; and the same condition was noted in Case II., ten days after the accident. The hearing in Case I. was normal, and in Case II. two-thirds. The possibility of his acuteness of hearing never having been up to the standard, may account for this apparently imperfect result.

The hemorrhage, if any was present at the time of the injury, had ceased before I saw the cases. Had any clots been present upon the membrane, it would have been proper to have carefully removed them, that the sides of the lacerations might have been brought into contact and plasma thrown out, so that the parts could unite, in the same manner as wounds of any other structure. In Case I. a drop of coagulated blood was noticed in the external auditory meatus, some distance from the membrane, which was removed for the sake of cleanliness.

The mechanism of the rupture is not difficult of explanation. The water, forcibly impinging upon the column of air in the external auditory meatus, suddenly increased its pressure upon the membrane, while the normal pressure upon the inside remained unchanged. The Eustachian tube permitted the air to escape from the middle ear, and thus it will be seen that there was no resistance given to the

[1] Arch. of Otology, vol. iii., 1872, p. 84.

internal column of air. The internal force of resistance being suddenly exceeded by the external impinging force, the rupture ensued. To prevent rupture when diving, it is necessary that the pressure upon the membrana from without should be compensated for by an equal resisting pressure from within. To accomplish this, a full inspiration should be taken prior to diving; the mouth kept shut; and, to prevent the escape of air by the nose, the posterior nares should be closed by elevating the soft palate. This is done almost involuntarily, and retains the inhaled air in the lungs, buccal and aural cavities, its compression being produced by the contractions of the chest and cheek muscles. The act of swallowing will force sufficient air, through the Eustachian tube, into the middle ear to resist the pressure from without.

Holding the nose is not essential to the closure above referred to, but is a crude method of accomplishing the same result, and is resorted to by those who either have not sufficient control over the palatine muscles, or who do so through fear of swallowing the water.

During the construction of the South Street bridge in this city, I spent some hours in one of the iron cylinders upon which the bridge rests, and was under a constant pressure of two atmospheres (thirty pounds to the square inch), and then learned the practical importance of increasing the density of the air within the ear cavities commensurable with the pressure from without.

The most common method of accomplishing the auto-inflation is by frequent swallowing with the mouth and nostrils closed; but the great difficulty experienced in repeating the act, without taking food or drink, makes its use inconvenient and often impossible. Valsalva's method of holding the nose and mouth shut and blowing is more practicable, as I found by experience.

It may be interesting to note that when the pressure was diminished, just prior to our coming out of the cylinder, the air in the middle ear escaped through the Eustachian tube in little spurts, and not in a full stream. This was undoubtedly owing to the valve-like action of the tube.

I believe that when rupture of the drum-head occurs in diving, the sudden application of the force is an important element in its production. If the force were applied gradually, time would be allowed to reinforce the membrana tympani by a cushion of air retained in the middle ear. It is not unusual for rupture to follow the discharge of heavy guns, and cases have occurred where a simple slap on the ear with a hand has been productive of the same result; in all such cases the mechanism appears to be the same.

In the great majority of cases there is only a simple slit, as in Case II., and the edges will readily coaptate and unite by the natural processes of repair. But when the rupture is more than a simple slit, I doubt if a perfect closure will ever occur without some such assistance as was afforded in Case I.

Valsalva, by a series of experiments upon dogs, abundantly demonstated the fact that a rupture or perforation of the membrana tympani is as capable of repair as wounds of other structures in the body, and practical experience with the human subject substantiates this statement. The results of lacerations of this structure are not as serious as might be imagined; for, besides her reparative power, nature possesses the faculty of ready adaptability to circumstances. The cicatrix that remains, in proportion to its extent, contracts and distorts the membrane, and renders it less pliable, and its appreciability for certain sounds may be impaired, yet its general usefulness is not materially changed.

I very well remember a classmate who, by an accident, was so unfortunate as to have a sharp lead-pencil point thrust through his membrana tympani. He had a few days previously carefully tested his hearing while trying to ascertain the hearing distance of his watch. Ten days after the accident referred to, it was found that his acuity of hearing was unimpaired.

After a rupture of the drum-head, if the parts do not unite, there will be left a permanent opening, and the inconvenience caused by air whistling through it is not the only thing to be dreaded. The delicate structure of the middle ear being directly exposed to the action and changes of the atmosphere, serious inflammatory changes are apt to take place, and purulent discharges and permanent impairment of hearing result.

The eye being exquisitively sensitive to the slightest touch takes cognizance of the presence of the most minute irritant, and prompts the patient to seek immediate relief. The absence of this sensibility in the ear is very frequently the cause of neglect to attend to it when injuries of this organ take place.

THREE CASES OF RETAINED PLACENTA.

By E. SANDERS, M.D.,

ATTENDING PHYSICIAN TO MT. SINAI HOSPITAL DISPENSARY, DEPARTMENT OF INTERNAL DISEASES, NEW YORK.

Cases of retention of the placenta, from one cause or another, are not so commonly met with that they are lacking in special interest, nor yet so rare as to be unworthy of particular attention, save as objects of our curiosity. Though all such cases are naturally characterized by the one important element—retardation in the expulsion of the placenta, yet the causes which bring about this delay, and the seat of this retention, vary greatly in the different cases. Thus morbid adhesion, abnormal or irregular uterine contraction, uterine inertia, unskilful or violent interference, etc., may produce such a result, while, as regards the situation of this retention, we may find the placenta still wholly within the uterus, or partly within the womb and partly within the vagina, or even entirely extruded into the vagina, as occurs in the so-called "student's placenta." It has been my lot during the past few years to meet with three such cases, differing in degree and kind, and dependent upon different and well-marked causes.

Case I. *Dead macerated fœtus in a primipara, softened and partly disorganized placenta, funis torn away, placenta retained by tonic uterine contraction.* —Was called in haste to attend Mrs. B., a primipara. Patient had been delivered of a dead, macer-

ated fœtus, after an easy labor under the charge of a midwife, having reached the beginning of the ninth month. Up to this point the labor had been perfectly normal, but the placenta not being immediately discharged, and there being some hemorrhage, she had attempted to forcibly deliver it by traction on the cord, having previously administered several doses of ergot. As a result, the funis had suddenly given way, the placenta remaining behind, the seat of rupture, as afterwards determined, being at its attachment to this organ. On arriving, I found the patient blanched, extremely feeble, emaciated, and almost pulseless. She had lost considerable blood, but when I reached her the hemorrhage had ceased, as had also all uterine pain. I immediately administered stimulants. A vaginal examination revealed the placenta partly within the vagina and partly within the uterus, being tightly grasped by this organ, which was firmly contracted around it, grasping it so that I found it impossible to hook it down with my fingers. Attempts in this direction also failed for the further reason that the placenta was so soft and friable as to break down on the slightest traction. I then attempted to deliver with placental forceps, but again failed, portions only coming away in the grasp of the instrument. My patient now being almost moribund, fearing the worst, and this being in my early practice, I requested a consultation. A professed specialist was immediately summoned, an aged and white-haired practitioner, who, after a hasty examination, announced that we were dealing with a case of adherent placenta; in fact, he stated it to be the worst case he had ever met. All this time uterine pain had remained absent, and all hemorrhage had ceased. The patient was placed under the influence of chloroform, and my adviser introduced his hand and withdrew piecemeal what he announced to be almost the entire placenta, informing me that he had scraped away all but a small piece, which was so firmly adherent as to render its removal impossible. Our patient's condition was now such as to indicate immediate danger of dissolution, but under stimulation she rapidly responded, and soon was comfortable. There was no consecutive hemorrhage. Receiving the statements of my consultant as correct, and considering the condition of my patient, although having my doubts, I failed to make any further examination. She was ordered continuance of stimulation and the use of carbolic acid injections. During the night she had some after-pains, and the next day, during a paroxysm of coughing, a mass of disorganized and stinking placenta, fully equal to one-third of the bulk of that organ, was suddenly extruded from the vagina, where it had probably lain for some time, and from that time on my patient steadily improved. Later on it was discovered that she had been suffering for fully a year from phthisis, which accounted for her weak and emaciated condition. A year after this she again miscarried at about the sixth or seventh month, and a few months later she died of phthisis complicated by chronic Bright's with general anasarca.

The points of interest in this case are: (1) the causes and seat of the retention; (2) the inability on my part to deliver by the fingers or forceps; (3) the error of my consultant.

The cause, or rather causes, undoubtedly consisted in part in the condition of the patient and the softened state of the placenta, but also in great part in the ignorance of the midwife. Unaware of the fact that she was dealing with a softened and partly disorganized placenta, but simply wishing to hurry up matters, she first administered ergot, and later made violent traction on the cord. The former agent produced tonic contraction of the uterus, probably just as the placenta was clearing the cervix, the result being that it was firmly grasped partly within and partly without the womb, while the cord, being soft and friable at this moment, suddenly was torn off. So much for untutored ignorance. Fearing that my patient would die on my hands, and being at the time a recent arrival in the medical ranks, I requested a consultation, after my own imperfect efforts had failed. A busy, professing specialist being summoned, overruled my diagnosis, and, announcing his belief here of a firmly adherent placenta, proceeded to deliver, claiming to have done so, with the exception of a small mass which he was forced, so he stated, to leave behind. The next day, this *small mass*, in the shape of about one-third of the placenta, was suddenly popped out during a fit of coughing. So much for tutored ignorance.

As for myself, my efforts proved unavailing simply because I feared to go ahead and do what I knew to be right and proper. Had I depended on self, I could easily have succeeded, since the case presented no special difficulties. The lesson which I learned from this case was that of self-reliance.

Case II. *Antero-lateral displacement of the uterus in a multipara following delivery of the child; retention of the placenta, followed by its expulsion on replacement of the womb.*—Mrs. C., æt. thirty-seven years, in labor with her eighth child. Her previous labors had always been tedious, but in other respects had been perfectly normal. In the present delivery, although the presentation and position were perfectly regular, and the parts well prepared, the first and second stages were rather slow and tedious, the pains being few and ineffective, delivery of the child not taking place until between twenty-seven and twenty-eight hours after the onset of the contractions, and this did not occur until ergot had been administered to whip up the lazy uterus. Hemorrhage but little more than usual. The placenta being slow to come away, a vaginal examination revealed the fact that it was still retained entirely within the uterus. Careful traction on the cord failing, I determined to employ Credé's method of expression, when, on placing my hand on the abdomen over the uterus, the cause of this retention was immediately made manifest, the uterus being markedly anteverted and twisted to the right. Reposition of the womb was followed by easy and rapid expression of the placenta by pressure, no pains occurring at the time. The interest in this case bears simply on the fact of the unusual cause of the retention: an antero-lateral displacement of the womb *after* the delivery of the child, but *before* the expulsion of the placenta. Although anterior displacement of the uterus before

the birth of the child, in multipara who have born many children, is not so uncommon; the condition existing in this case seems to be very rare, for, as far as I am able to determine, obstetrical writers are silent on this subject. Presumably, therefore, uterine displacement sufficient to retard the delivery of the placenta, after the child has been born, has not been met with by such authorities, and its special mention here is of manifest importance. Its detection was not difficult, and the remedy easily applied; its gradual and careful reposition being safely accomplished by external manipulation alone. The causes of this condition existed in the exceedingly relaxed state of the patient's abdominal walls, dependent upon frequent and rapidly recurring pregnancies, as also upon the inefficient uterine contractions, this organ remaining somewhat flabby throughout, not contracting firmly until the placenta was expelled. To indicate how rapidly impregnation has occurred in this patient, I need but to state that, while at present carrying about a child of four months, the next eldest being but fifteen months of age, she is now in the second month of gestation with another. A relaxed abdomen in such a subject can easily be understood.

Case III. *Almost universally adherent placenta in a multipara; great hemorrhage; syncope; delivery by scraping out the uterus; recovery.* — Was called about 7.30 o'clock on Sunday morning to attend Mrs. U., a multipara, æt. thirty-two years, who, I was informed, had been in labor since six o'clock. On my arrival, I found that the membranes had ruptured, and the head was well down in the excavation, the pains being strong and efficient, the presentation and position normal, the parts relaxed, and everything progressing favorably. My patient was observed to be emaciated and apparently very feeble, and I was informed that she had been so weak before labor set in as to be unable to walk. She had suffered some months from an aggravated cough. However, the child was safely delivered at about eight o'clock, its expulsion being immediately followed by great hemorrhage. The child itself was covered from head to foot with stringy and small rounded masses of coagulated blood, a rather unusual circumstance. The uterine pains continued, but without effect either in arresting the hemorrhage or in expelling the placenta. An attempt was therefore rapidly made to deliver it by traction on the cord; but as moderate pulling on this was followed by an appreciable giving way of its structures, this was soon desisted from, it being noticed during this attempt that, on cessation of the traction, the cord was felt to return as far as it had previously yielded, at the same time conveying the impression to my hand of pulling on some unyielding body, and convincing me that the placenta had not descended in the least, but was still retained entirely within the uterus, the cause as yet being unsuspected. Thinking then to employ Credé's method, the hand was placed on the abdomen; the womb was found hard and contracted, large, and globular in shape. All efforts to deliver the placenta failed. Still, in spite of these symptoms, I did not for a moment imagine that I was dealing with a case of adherent placenta; but knowing that here was an instance of dangerous hemorrhage, and feeling that if this was not quickly arrested my patient must die, other means having failed, I rapidly introduced my hand into the uterus, the vagina being found full of clots, when the cause of the bleeding was immediately manifested: the placenta, with the exception of a small portion along the lower segment of the womb, being firmly adherent to the uterine walls. The hemorrhage at once ceased, the uterus contracting rigidly upon my hand. As carefully as possible I proceeded to peel off the placenta, which, adherent along the left antero-lateral wall, was found most firmly attached at the left cornu. The patient lying at the left edge of the bed, and it being impossible to move her, I was forced to employ my left hand; hence, I was working at a disadvantage, more especially as the placenta itself was adherent on the same side. After persisting for fully three-quarters of an hour, and having several times withdrawn my hand, my wrist becoming tired and cramped from the constant contraction of the uterus upon it, I was forced to desist; Dr. Bleything, who had kindly come to my assistance, peeling off the small but very firmly adherent portion at the left cornu, which I had been unable to remove. A few shreds we were forced to leave behind on account of the condition of our patient, she having had one attack of syncope, from which, however, she rallied after copious doses of brandy. Throughout our manipulations it was found necessary to constantly stimulate her, brandy being administered almost *ad. lib.* She became several times pulseless, and received ♏xxx of the tinct. digitalis hypodermically, to which she responded nicely, later on receiving a second injection of ♏xx. The fl. ext. of ergot was also given on two occasions in ʒj doses. Nevertheless, after delivery of the placenta, the uterus contracted imperfectly, necessitating the keeping of my hand over the fundus for between two and three hours, and frequently stimulating it to contraction, which it usually did, by rubbing and pinching it, a slight hemorrhage occurring intermittently. Ice was also placed in the vagina, and finally the uterus contracted firmly and all bleeding ceased. No chloroform was administered. During these entire proceedings the patient had lain cold and exsanguinated, perfectly passive and completely unconscious of her surroundings, continuing in this condition for fully an hour after the bleeding had stopped. Stimulation was continued, and as she became restless, sol. morph. sulph. (U.S.) was given in quantities sufficient to quiet her.

During the day she continued steadily to improve, her temperature the next morning standing at 100¾° in the axilla, rising to 102° in the evening. Slept some during the night, taking also a little nourishment. Carbolized douches were ordered to be used three or four times a day. The lochial discharge was free and as yet not fetid, some shreds of the placenta coming away in it. Treatment was by stimulants, tinct. of digitalis, ♏v., q. 4 h., careful attention to diet, and absolute rest with the head

lying low. This improvement was found the next day to have continued. Some after-pains had occurred, and there was some slight pain on pressure over the uterus, with slight difficulty in micturition, and she complained of feeling excessively weak. The lochia good, not yet fetid, and containing a few fragments. From this time on until the sixth day the improvement was uninterrupted by any bad symptoms, the temperature ranging in the neighborhood of 101°, all pain ceasing, the bowels moving regularly, the appetite becoming better, the lochia abundant though slightly fetid, more especially in the morning, and still containing a few shreds and on one occasion streaks of blood. On the sixth day the temperature suddenly rose to 103°, the explanation for this being found in the unexpected appearance of milk in the breasts. Belladonna ointment was applied freely to the breasts, and quinia given internally, and after a few days the milk vanished and with it disappeared all febrile symptoms. There was no further interruption to a slow but steady recovery, save an attack of syncope on the fourteenth day, due to the indiscretion on her part of sitting up in a chair contrary to orders.

In her previous confinement, which was with twins, two years before, patient informs me that the attending physician stated to her that a small part of the after-birth had "grown to her side," and that he had failed to bring it away. A few days thereafter several fragments were observed to come away, probably portions of the placenta, which seems to bear out this statement.

During gestation with the present child she had been almost constantly ill, for the last four months suffering from a persistent cough with copious expectoration, emaciation, sleeplessness, loss of appetite and strength, but no hæmoptysis; probably a chronic bronchitis. She also noticed a pain low down in the left iliac region, most marked on turning on the right side in bed, often waking her with a scream out of her sleep, so intense was it at times; this having existed during the entire latter half of gestation.

Cases of morbid adhesion of the placenta are confessedly very uncommon, for such is the uniform statement of authors on this subject. The principal and most important difficulty to be overcome in this condition lies in its diagnosis, since, this being made, the indications to be met are plain and simple, and easily carried out. The symptoms, unfortunately, are usually indefinite and not apprehended, the diagnosis generally remaining unmade until the hand has been introduced into the uterus; such, at least, was true of my case. Cazeaux (*Theoret. and Pract. Treat. on Midwifery*, Phila., 1873, p. 876; trans. by Bullock), who gives the best description of this trouble I have met with, sums up the signs and symptoms of placental adhesion as follows:

"Whenever a considerable period of time has elapsed after the labor, without the delivery of the after-birth being effected, and yet the globular form of the uterus, its hardness, and manifest contraction, clearly show that it is striving to detach and to expel the secundines, and where the finger, passed through the cervix uteri, does not detect the placenta, we have every reason to suppose that there is an unnatural adhesion of this mass. The following signs will then confirm our suspicions: after drawing on the placenta by means of the cord, the latter will be found to mount up as soon as it is relaxed; during the contraction the uterine globe becomes harder and diminishes in volume, but after the pain is over it returns to its former condition much sooner and more perfectly than in other cases; and lastly, the existence of this complication is rendered unequivocal by carrying the hand up into the uterus."

It will be observed that in my case all these symptoms were present with the exception of that referring to the change in volume of the womb; but it was not until the last, the introduction of the hand, had been resorted to that the condition of affairs was made out; and this I conceive to be the rule in such cases. Up to this time abnormal adhesion of the placenta had not been suspected, and it was only when the adhesions were actually felt that the diagnosis was reached.

The extent of the lesion is also of interest, since, with the exception of a small segment at the lower part, which appeared to have been detached by the uterine efforts, judging by the hemorrhage that occurred after the birth of the child, the placenta was entirely adherent. Slight adhesion appears to be comparatively not so rare, while its existence to as great a degree as in the present instance I presume to be very uncommon.

As regards the causation, I find myself unable to decide. The patient was in a very much reduced condition, due to an exhausting cough from which she had suffered for months. It will be remembered that there was a history of slight adhesion in her previous pregnancy, during which she had been perfectly well. In neither case was there a history of the slightest injury. She had observed during the present gestation an intense, fixed pain, most marked on turning on the right, over the left side of the uterus, which may possibly have indicated some form of inflammatory change going on in the placenta or its membranes, probably a placentitis, for it was along this wall, as we know, that the placenta was located. Unfortunately this organ was thrown away before I had an opportunity to examine it, hence its condition and the cause must remain unsettled.

MALIGNANT HEPATIC GROWTH PRODUCING SYMPTOMS SIMULATING SCIATICA AND MUSCULAR RHEUMATISM IN THE LEFT LEG.

By BOARDMAN REED, M.D.,

PRESIDENT OF THE ATLANTIC COUNTY (N. J.) MEDICAL SOCIETY, AND PHYSICIAN TO THE SEASIDE HOUSE FOR INVALID WOMEN AT ATLANTIC CITY.

The following case illustrates the importance of searching carefully for obscure or remote causes in all cases of unusually obstinate disease.

Mrs. M., aged somewhat over fifty years, the wife of a Philadelphia clergyman, entered the Seaside House for Invalid Women, early in February, 1882. Upon admission she had a cachectic appearance, and was much emaciated. She walked with great difficulty owing to lameness of the flexor and ad-

ductor muscles of the left thigh. Her bowels were somewhat constipated and her appetite poor. She had been under treatment by a reputable physician, in Philadelphia, for several months. In accordance, therefore, with my rule to continue as far as practicable the line of treatment pursued by the attending physician at home, especially when the case is chronic and the sojourn at the seashore to be short, I desired her to obtain from her physician a brief statement of what he had been doing for her. This was done. The former attendant very courteously wrote me a clear history of the case as then developed. The following is an extract from his statement:

"Mrs. M. came under my care early last October. I found her suffering from subacute inflammatory rheumatism complicated with sciatica. The rheumatism gave way to treatment very readily; also the pain in the nerve. But I found then a want of nerve power in the left limb—the limb affected by the sciatica. My treatment for this has been directed mainly to building up the general health, with some remedies directed to the nerve. The former has mainly been the preparations of cinchona (the alkaloids cinchona, cinchonidia and quinia) with iron, the carbonate and prussiate. To meet the condition of the nerve, she has taken fluid extract of cimicifuga; also pills of iodoform and iron. These were not given simultaneously. She took one remedy say two weeks, then changed to the other."

By the way, it would be well, if all invalids sent to health resorts were furnished with such statements by their medical advisers, especially when still continuing medicines; since they are very often obliged to consult a resident physician, even when this has not been anticipated, and in that event a note explaining the treatment the patient has had may prevent useless if not injurious experimenting with remedies whose effects have been already exhausted or concerning which there are idiosyncrasies.

To return from this digression; a week after Mrs. M.'s admission her lameness had rather increased, though her appetite had somewhat improved. A cursory examination revealed some tenderness at the point of emergence of the left sciatic nerve from the pelvis, and much pain upon movement of the flexor muscles of the thigh on the same side. There was but little pain while she sat or lay still, but though she was a woman of much determination, locomotion was almost impossible for her, even with the help of two stout canes.

The tonic treatment was continued, and small flying blisters were placed on the tender points over the sciatic, and later along the line of the crural nerve. These seemed to afford some slight temporary palliation only. Strong rubefacient liniments were freely used, also on the same regions without result. Some lameness gradually developed in the right thigh also, though it never became so marked as in the left.

It was evident to me that there must be a deep-seated cause for so obstinate and progressive a condition. Such a contracture as was presented on the left side could only be produced by some irritation of the crural nerve, most likely pressure upon it. A rheumatic affection of its sheath would probably have been more favorably influenced by the blistering. Inquiries were made as to symptoms of uterine derangement, but with a negative result. She had always been singularly exempt from the pelvic pains so common in women during the child-bearing age. Still a vaginal examination was insisted upon, and finally permitted. It revealed a hyperinvoluted uterus, which was retroflexed, and with the adjacent structures forced down, as by some pressure from above, to the floor of the pelvis. I found it impossible to pass even one finger into the Douglas culde-sac, so tightly was everything jammed down in that locality. The cervix seemed perfectly healthy. Bimanual palpation discovered the cause of the jam. There was found an abnormal prominence and hardness in the hypogastric and right iliac regions. Percussion showed this hard body to be continuous with the liver. Its thin edge apparently smooth, not nodulated, could be plainly felt, on careful palpation, some four inches below the umbilicus in the median line extending still lower to the right. Three inches below and two inches to the right of the umbilicus there seemed to be a marked thickening of the tumor, which presented a prominence at that point plainly apparent on inspection. The tumor descended with every inspiration, and was not in the least tender on pressure. No pain whatever had been experienced in the liver or abdomen, and there was no jaundice. Even the constipation was not at all obstinate.

The patient seemed to have no suspicion that a tumor existed, even after my examinations. It was ascertained, however, that a growth of some kind had been removed from one of her breasts ten years previous by Dr. John Neill. I examined the cicatrix, and found it beginning to ulcerate.

I considered the abdominal tumor to be a malignant enlargement of the liver, which had crowded the intestines and pelvic organs downward, and especially to the left, thus producing pressure upon the great nerve trunks upon that side more particularly.

The patient was shortly afterward removed home, her husband being informed as to the nature of her malady, and that no improvement was to be expected. Some weeks later she was seen in consultation by Dr. William Goodell, who writes me as follows:

"I saw Mrs. M. for the first and last time on April 17. She was then bed-ridden, very much emaciated, and also jaundiced. Nothing was said to me about her lameness, and I believe that I did not make a vaginal examination. I found, however, a large bossellated tumor, which seemed continuous with the liver, and which I believe to be a malignant hepatic growth."

Shortly after this consultation her death occurred, and I cannot learn that any autopsy was made.

The interesting features of this case are (1) the exceptionally long period which elapsed after the removal of the tumor in the breast before its recurrence; (2) the remarkable absence of pain and of symptoms of hepatic obstruction until within a few

weeks before death; and (3) the transmitted pressure, causing irritation of the sciatic and crural nerves, especially upon the left side, which, however, may, of course, have been due to small cancerous growths in the pelvis.

MEDICAL PROGRESS.

Amputation in Senile Gangrene.—Mr. N. C. Dobson formulates his views as to the advisability of amputation in senile gangrene as follows:

1. He would not amputate in those cases where the patient's strength was fairly good, where there was a fair prospect that a line of demarcation would be formed, where he was not suffering great pain, or where the pain was readily controlled by small doses of opium, and where symptoms of septic absorption were absent.

2. He would advise amputation in all those cases where the patient was not extremely aged— *i.e.*, over seventy-five or seventy-six—in which the pain was very severe, the grangrene rapidly spreading, and in which marked symptoms of putrid poisoning were manifesting themselves; and he would amputate irrespectively of the patency or otherwise of the main artery at the spot selected for amputation—preferring, of course, patency.

3. In cases of amputation under such conditions as he has mentioned, he would amputate above the knee for gangrene of the leg, above the elbow for gangrene of the hand or forearm. Even when the main artery is blocked, the collateral circulation is generally sufficient to carry on the nutrition of a comparatively short stump. This is his reason for a comparatively high amputation. The mere fact of the possibility of rapid healing of a large stump in even very old persons is a sufficiently well established fact in surgery to need no comment. The point he would further insist on is that, with antiseptic precautions, there is usually a minimum stress laid upon the powers of repair, which is especially useful in dealing with such cases as those we are now considering.—*British Medical Journal*, July 22, 1882.

The Duration of Isolation of Subjects of Contagious Diseases.—M. Hillairet, in the name of a Commission composed of MM. H. Roger, Bergeron, and Hillairet, read before the Académie de Médecine a report in reply to the inquiry addressed to the Academy by the Minister of Public Instruction, as to how long a pupil affected with a contagious disease should be kept away from school.

The report considered the following diseases: varicella, variola, scarlatina, rubeola, mumps, and diphtheria, and the conclusions are as follows:

Varicella, whose progress is often irregular, may require ten to twelve days for the fall of the crusts: The isolation should be about twenty-five days.

Variola has a prodromic period of three to four days; four or five days of eruption; three or four days of suppuration; desiccation requires three days; fall of the crusts, six days. Then comes a period of furfuraceous desquamation without definite limit. Isolation should not be less than forty days.

In scarlatina the period of invasion occupies from six to forty-eight hours, or exceptionally three days: the eruption is completed in from five to eight days; desquamation commences on the fourteenth or fifteenth day, and lasts from fifteen to twenty-six days. Isolation should last forty days.

Rubeola has a prodromic period of three to four days; exceptionally, from six to eight, or even twelve days; the eruption is completed in twelve or forty-eight hours, then it declines for twenty-four hours; desquamation lasts from eight to fifteen days. Isolation for forty days will be sufficient.

Mumps, as a rule, has a duration in ordinary cases of six days; convalescence lasts from six to seven days. If any complication of metastasis occurs, it lasts usually about nine days. Isolation for twenty-five days is sufficient.

The duration of diphtheria is very variable, but isolation should be maintained for at least forty days.

The Commission consequently proposes the adoption of the following measures.

1. Pupils affected with chicken-pox, small-pox, scarlet fever, measles, mumps, or diphtheria, should be strictly isolated from their comrades.

2. For small-pox, scarlet fever, measles, and diphtheria, isolation should not be shorter than forty days; for chicken-pox and mumps, twenty-five days is enough.

3. Isolation should last until after the patient has been bathed.

4. The clothing worn by the patient at the time he was taken sick, should be subjected to a temperature of 90° C. [194° Fahr.], and to sulphur vapor and then well scoured.

5. The bedding, curtains, and furniture of the sick-room should be thoroughly disinfected, washed, and aired.

6. The pupil of a school, after recovery from one of the above contagious diseases, should not be readmitted to the school unless furnished with the certificate of a physician that the above precautions have been observed.

These conclusions were adopted by the Academy.—*Gaz. Méd. de Paris*, July 22, 1882.

Iodoform Poisoning.—Mosetig has used iodoform in Listerism in 7000 cases and has not met with poisoning. He explains this immunity by (1) his never employing it in large quantities; (2) by never causing pressure upon it in a wound; (3) by his rarely changing the dressings; (4) by never washing the wounds in dressing them (since absorption takes place more rapidly in granulating than fresh wounds); (5) by his using only pure materials—*i. e.*, iodoform alone; the combination with carbolic acid is dangerous, since the latter is always liable to irritate the kidneys, and may thus hinder the excretion of the iodine set free within the body and give rise to its accumulation in the blood.—*Maryland Medical Journal*, August 1, 1882.

The Third Blood Corpuscle.—The last published number of the Bulletin of the Royal Academy of Medicine of Rome contains a memoir by Prof. Legge, entitled "Observations on the Blood of the Salamander, and of the Triton, concerning the Plates (*piastrine*) of Bizzozero, and the invisible Corpuscles of Norris." We give a literal translation of Prof. Legge's conclusions on this important matter. "1. In the blood of tritons and salamanders, in addition to the white and the red corpuscles, exists a special morphological element, which, if not identical with, is at least analogous to, the blood plates (*placche di sangue*) of Bizzozero. 2. In the preparations of the same blood are to be seen colorless disks, which correspond to the description which Norris gives of his invisible corpuscles. 3. These disks are the result of an operation which the red corpuscles undergo in the presence of water. This confirms what Bizzozero asserts concerning the absence of Norris's invisible blood corpuscle in mammalia. 4. The alterations which red corpuscles undergo in the presence of water are the solution and effusion of the hæmoglobin, the transformation of the nucleus, from the original oval, into a brilliant sphere, and the softening of the

cellular membrane, which finishes by disappearing, leaving free the nuclei, which remain separate and floating in the liquid."—*Lancet*, July 22, 1885.

New Method of Treating Salivary Fistulæ.—At the meeting of the Société de Chirurgie, held July 5th, M. Delens read a report on a work of M. Richelot on this subject. His method consists in forming an internal orifice to the fistula by tying the thickness of the cheek in the grasp of an elastic ligature; after the ligature has cut through, the external orifice closes of itself while the other remains open.—*Le Progrès Médicale*, July 8, 1882.

Treatment of Dyspepsia.—M. Sassezki (*Journ. de Méd. d'Algerie*) has determined, in the cases of three patients suffering from chronic gastritis and four healthy persons, during a phase of profuse sweating, the degree of acidity of the liquid taken from the stomach, the digestive power of the latter on fibrine, and the amount and the degree of acidity of the urine. He found that the sweats weakened the digestive power of the gastric juice, reduced at the same time its acidity, and that also of the urine; and this the more energetically the more abundant the perspiration was. From the practical point of view, the author inquires if, amongst dyspeptics subject to perspiration, it would not be well to try atropine to diminish the perspirations, and to increase, at the same time, the acidity of the gastric juice. He, likewise, is of opinion that this same acidity might be increased by rendering the urine alkaline by means, for instance, of a vegetable diet. He throws out the suggestion, whether the instinct which induces the inhabitants of hot countries to instinctively prefer a vegetable diet, is not to be found here.—*London Medical Record*, July 15, 1882.

The Nervous Symptoms of Myxœdema.—From a careful study of this subject, Dr. W. B. Hadden concludes:

(1) That in the early stages myxœdema is essentially a disease of imperfect nutrition, dependent probably on generalized angiospasm.

(2) That the solid œdematous condition of the skin and connective tissue is due to a form of lymphatic obstruction, which may also be ascribed to vaso-motor influence; and that the accumulated products undergo changes which result in the formation of mucin.

(3) That the condition of the thyroid gland is also to be explained on the vaso-motor hypothesis.

(4) That the more severe mental symptoms, such as insanity, occurring in the later stages of myxœdema, are due to alterations in the brain itself.

(5) That, although myxœdema is a distinct morbid entity, it is probably intimately allied to certain other disorders, such as sporadic cretinism and scleroderma.

(6) That the solid œdema, which is universal in myxœdema, may be localized in various parts of the body, such as the tongue and extremities.

(7) That the primary and essential lesion probably exists in the peripheral sympathetic system, and perhaps, too, in the supreme centre in the medulla oblongata, this last supposition being based on the occasional occurrence of bulbar symptoms in myxœdema.—*Brain*, July, 1882.

Locomotor Ataxy of Syphilitic Origin.—Vulpian (*An. de Dermatologie et Syphilogie*) thought that about forty per cent. of cases of locomotor ataxy were of syphilitic origin. Fournier has just demonstrated that, far from being exaggerated, this statement is rather below the truth—in nearly all he finds a syphilitic source. The practical results of this view are embodied in the following conclusions:

1. In a case of locomotor ataxy seek carefully for syphilis.

2. If this diathesis exist, institute severe and prolonged treatment. Endeavor to surprise the commencing tabes, and watch the least symptom which can indicate its invasion.

3. The fear of ataxia later ought to be considered in the treatment of the initial stage of syphilis, which ought to be treated for a long time energetically.—*Maryland Medical Journal*, August 1, 1882.

Symptomatology of Cystic Degeneration of the Kidney in the Adult.—Communications on this subject are rather scarce in medical literature; clinical observations are rare, but *post mortem*, accidentally, numerous examples are found, symptoms indicative of which have not been noticed during life. In other cases, phenomena similar to those of chronic Bright's disease precede the fatal exit of the patient, or symptoms pointing to some form of renal lesion have been noticed, but passed over as unimportant. A case related by Strübing (*Deutsches Archiv für klin. Med.*, 1882) was that of a woman aged 51, who had been in very good health until her forty-first year, in which hæmaturia, with pain in the region of the kidneys, was followed by progressive marasmus. Nothing beyond hypertrophy of the left ventricle and enlargement of both kidneys could be made out, and albumen was only temporarily present now and again. At the *post-mortem* examination, it was found that, instead of the carcinoma it was expected to reveal, the enlarged kidneys had undergone a total change of structure, being about 20 centimetres (7.8 inches) long, and containing numerous large and small cysts, some of the size of a hen's egg. The contents, on analysis by Baumstark, were found to consist of—1, cholesterine; 2, two albuminous bodies, namely, serum-albumen and a globuline; 3, six grammes of urea to every 100 cubic centimetres of the fluid. Uric acid, leucine, and tyrosine were not present.—*London Medical Record*, July 15, 1882.

Suppositories of Ergotin.—At a recent meeting of the Société de Thérapeutique (*Bull. Gén. de Thérap.*, vol. ii., 1880, p. 43) M. Dujardin Beaumetz stated that, following the example of a Belgian physician, he had attempted the employment of ergotin in suppositories to combat the metrorrhagia of uterine fibromata. These suppositories contained fifty centigrammes (eight grains) of ergotin—that is to say, about five times the amount used in hypodermic injection. He had obtained excellent results in two cases, which had been cured in the first after two applications, in the second after three applications.

In the discussion following, M. Ferrand said he also had employed these suppositories in studying the influence of ergotin on hemorrhoids. One patient, among others, had been relieved of a persistent hemorrhoidal flux after the employment of eight or ten suppositories containing twenty-five centigammes of extract of ergot. This patient had had no return of the flux after more than a month.

M. Vidal said he also had used these suppositories in the treatment of rectal prolapse. He was accustomed to use suppositories containing fifty centigrammes to a gramme of ergotin. The effect obtained had not been as satisfactory as in using hypodermic injections; besides which the patients complained of a very painful burning sensation in the neighborhood of the anus.

M. Ferrand said the dose was not without importance, because of the great difference of sensibility which exists between the mucous membrane of the stomach and that of the rectum: thus, saline enemata

which caused energetic and painful contractions of the intestines produced no such effect when introduced into the stomach. In the patient suffering with hemorrhoids, whose case he had reported last year, he had employed hypodermic injections of ergotin after having been obliged to give up suppositories of tannin, which had been badly borne.

M. Moutard Martin believed that there existed an undoubted difference between the stomach and the rectum with regard to their relative sensibility; besides, the intestinal mucous membrane absorbs more easily, rendering it necessary to use smaller doses than by the mouth. The example selected by M. Ferrand was ill-chosen, because the saline solution employed as an emetic also excites the gastric mucous membrane greatly; but chloral, so well supported by the stomach, often causes severe pain when given in enemata.

M. Dujardin Beaumetz thought that suppositories of ergotin were to be recommended as useful in uterine fibroid. They did not present the same danger as the parenchymatous injection of ergotin in solution into the uterus, which is sometimes followed by fatal peritonitis. The formula for the suppositories might be fixed, for example, as ergotin fifty centigrammes, ol. theobromæ five grammes.

M. Ferrand thought that if these suppositories gave pain they might be reduced in strength and repeated more frequently.

M. Blondeau had employed similar suppositories in a case of retention of urine, and had obtained good results.—*Canada Medical Record*, July, 1882.

Sulphurous Acid in Tuberculosis.—Some experiments by Froschaner on the treatment of septicæmia by sulphurous acid, suggested to Catani the trial of this agent in phthisis, and his experiments are of interest, not only from this practical aspect, but also in connection with the discoveries of Koch. Phthisical patients were made to drink of water impregnated with it, and especially were made to breathe in closed rooms the air of which contained a considerable quantity. The experiments, continued for a considerable time, yielded the following conclusions: Most patients bear the long-continued inhalation of sulphurous acid remarkably well; only during the first few days, before they have become accustomed to it, do they complain. All the cases thus treated became free from fever in the course of a few days, and subsequently remained so. As far as could be ascertained, the local mischief showed no tendency to increase during the treatment, and the amount of expectoration became slighter. The observations are being continued in order to ascertain how far a permanent effect can be produced.—*Lancet*, July 22, 1882.

Diagnosis of Vesical Calculus.—Volkmann's investigations (*Centralb. f. Chir.*, No. 11) on the diagnosis of stone in children is of importance to the general practitioner as well as to the surgeon especially interested in the treatment of these cases. He states that the rectal bimanual examination for stone is of great value. The patient is thoroughly placed under the influence of an anæsthetic until the abdominal muscles are completely relaxed. The bladder is to be empty or but slightly distended; two fingers of the left hand are to be carried as high up into the rectum as possible; the right hand presses upon the abdomen above the symphysis pubis and forces the bladder down towards the rectum until both hands meet. In this way even small calculi can be readily detected, but it needs considerable practice and experience to determine the size of the stone, Volkmann finding at first that the stone turned out to be larger on extraction than he had expected on examination, although distinctly feeling it between his fingers. The best way to determine the size is to lift it up on the os pubis and hold it there; this Volkmann has done in his last four cases, the last stone which he palpated in this manner being as large as a chestnut.—*Boston Med. and Surg. Journ.*, July 27, 1882.

Antiseptic Treatment of Phthisis.—In a volume which he has just publishd on the *Therapeutics of the Organs of Respiration*, Prof. Oertel, of Munich, devotes about 350 pages to the subject of "Inhalations;" in which he speaks highly of the use of a five per cent. solution of benzoate of soda, atomized—*i. e.*, inhaled in the form of fine spray. He has observed a very cleansing effect to follow its use in the ulcerative lesions of laryngeal phthisis; and he infers, from this, that a similar favorable action may be exercised on the lesions of more deeply seated parts; on the bronchial ulcerations and softenings, and on the walls of cavities. The expectoration is facilitated—increased at first, and subsequently diminished. Mycotic processes and decomposition of the secretions are arrested; and the absorption of secretions is thus favorably modified, and is less likely to be pyrogenic or specifically infective. He also points to the importance of thorough cleansing of the mouth and fauces; the appetite is thereby improved, and the stomach is spared the infliction of decomposing oral secretions. The swallowing of a certain amount of the solution he considers of great value, as he believes it operates in diminishing the fever. He duly discredits the marvellous results claimed for this plan of treatment by Rokitansky; but sees no reason to deny the correctness of Schüller's impressions, as to the results of his experiments on animals, performed under conditions very different from those obtaining in the subjects of advanced phthisis. He, moreover, expresses a confident belief that, by this and other antiseptic mode of inhalation, very good effects will be attainable.—*British Medical Journal*, July 22, 1822.

Resorcin in Diphtheria.—Andeer, who has employed resorcin in so many diseases, has recently used it in diphtheria, and states that, in the slighter forms of the disease, a single cauterization with crystalline resorcin, or with a concentrated ointment of resorcin in vaseline, is sufficient to arrest the formation of false membrane; but in cases of greater severity repeated applications are necessary; while in the most severe forms of the disease he recommends that resorcin should be given internally as well as applied locally. We fear, however, that his recommendation of the drug must be received with some caution, since he makes the extraordinary statement that of 222 cases treated thus, not one died. If his diagnosis of the disease was correct in one-tenth of his cases, the result would still be satisfactory. He asserts that the agent appears to be a true specific, influencing the morbid blood state as well as the local process.—*Lancet*, July 22, 1882.

Location of the Muscular Sense.—Westphal (*Charité-Annalen*, 1882) reports a case which throws some light on this subject. The patient was a man, aged 38, who in July, 1879, suffered from delirium tremens. From this he recovered, but on August 7th he became aphasic without losing consciousness. On August 14th, and again on August 19th, he was convulsed on the right side and had symptoms of the so-called atactic and sensory aphasia, but did not lose consciousness. And lastly, on November 13th, he was unconscious for a short time, and was temporarily paralyzed in the right arm. In all of these attacks the motility of the right extremities seemed deeply impaired, but it is difficult to say how far the appearances

were due to actual motor weakness, and how far to the inability to originate a suitable nervous impulse; in other words, to a defect of volition. There was undoubtedly some motor weakness, but it was not permanent, and in a short time the patient always recovered his muscular strength.

But in addition to these motor symptoms there were sensory symptoms, and these were permanent. They were observed with great minuteness from October, 1879, to December, 1881 (when the patient died somewhat suddenly), and were never found to exhibit much variation. There was a marked impairment of the muscular sense of the right upper extremity. The right hand was used very clumsily, and the patient seemed unconscious of the position of the upper extremity and of the movements it made. In the right lower extremity there was scarcely any affection of the muscular sense. Sensibility was diminished in the right side of the body and in parts of the face. There was bilateral right hemianopsia.

The *post-mortem* revealed a lesion implicating the whole of the parietal lobe (including the ascending parietal convolution), the greater part of the occipital lobe, and a small portion of the temporo-sphenoidal lobe. Here the pia was adherent to the cortex, the gray matter was softened, and of a yellow color, and the convolutions were atrophied. The atrophy was less noticeable in the posterior part of the angular gyrus than elsewhere. The cortex only was involved. The rest of the brain was normal. This condition of the brain reminds us of general paralysis, but Westphal is of opinion that the two processes are essentially different.

Westphal attributes the hemianopsia to the lesion of the occipital convolutions. He is unable to say whether the loss of muscular sensation is dependent on the lesion of the ascending parietal convolution or on that of the remaining parietal convolutions.—*Brain*, July, 1882.

Injection of Medicated Substances into the Lung-tissue.—Records of experimental attempts to deal directly with the lung-tissue, whether for the treatment of existing disease or for physiological purposes, are to be found but sparingly in medical literature. Dr. E. Fraenkel records (*Deutsche Med. Woch.*, No. 4, 1882) a whole series of experiments made with a view to the study of the effects produced by the injection into the lung-tissue of various medicated substances: 1. Upon the local tissues. 2. Upon the general organism. He used the following substances: carbolic acid, in a strength of 1, 2½, 4, and 5 per cent.; 4 per cent. watery solution of boracic acid; 5 per cent. of iodoform in olive-oil; 2, 4, and 5 per cent. solutions of acetate of alumina. Rabbits were used for the experiments, and the injections were made with a syringe fitted with a very long and fine canula. The number of daily injections varied from one to six, and the amount injected each time was always the same, 1 gramme. In hardly any case was there any reaction produced, a slight cough here and there being the only symptom. Even when the animals were kept alive for weeks, no changes took place which could indicate any spreading affection of the parenchyma of the lung, and physical examination invariably gave a negative result. Some of the animals gained considerably in weight. The pathological results obtained are classed as primary and secondary. The first consisted of hemorrhage into the lung-tissue and into the pleural cavity; but in neither case was it of importance, for the most part becoming absorbed, and in only one or two cases leaving a slight pleural adhesion. The secondary results consisted of local infiltrations and cellular proliferation in the lung-tissue, but in every case these were found to remain local, and to show every tendency towards healing. From the stand-point of these experiments, and from certain other clinical facts, Dr. E. Fraenkel states his conviction that the human lung, also, will come to be regarded as an especially adapted organ for the reception, by parenchymatous injection, of antiseptic remedies. Cases of progressive chronic phthisis he regards as particularly indicative of this method of treatment, especially in the earlier stages of catarrh and infiltration of the apex; and he looks to it to alter the character of the inflammation in the already affected spots, and to assist the natural tendency of the healthy tissue around to throw out a protecting barrier of inflammatory material. In cases, also, of gangrene of lung and putrid bronchitis, the injections might be of service. In one case of this latter kind, injections of five per cent. carbolic lotion were employed, and, although no improvement was observed, there was also no trace of any injury having been suffered by the lung.—*London Medical Record*, July 15, 1882.

Resection of the Pylorus in Italy.—This operation has just been performed for the first time in Italy by Professor Caselli, of the University of Genoa. The patient was a female, who had been admitted to the hospital with symptoms which pointed to closure of the pyloric orifice of the stomach by a neoplasm presumably of a carcinomatous nature. In the operation itself there was no feature of particular interest, except the severe shock from which the paient suffered almost from the first incision. The time occupied was two hours and a half. To secure the stomach to the duodenum, and to sew up the organ itself, about fifty sutures were employed. The portion excised was elliptical in form, and measured four inches and a half in length by three and three-quarters in breadth. The operation itself, in all its details, was successfuly completed; but the patient unfortunately sank from shock a few hours after her removal to the wards. The necropsy confirmed in every respect the correctness of the diagnosis, and showed, moreover, that all the other viscera were perfectly free from cancerous infiltrations. The operation, therefore, was a thoroughly legitimate one. Moreover, from the excellent position in which the stomach and duodenum were found after death, there is little doubt that, had the patient's vital powers held out, the result would have been a most brilliant one.—*British Medical Journal*, July 1, 1882.

Operative Treatment of Necrosis of the Vertebræ.—M. Boeckel reports the case of a woman, aged forty-three years, in whom an abscess formed between the left scapula and the vertebral column. On opening it, it was found that the third rib was necrosed and a piece four centimetres long was resected; on further exploration of the wound, the lateral half of the bodies of the second and third vertebræ were found to be carious, and a quantity of dead bone was gouged out, and antiseptic dressings applied. Three months afterwards, although the wound was not completely healed, the woman's condition was greatly improved. —*Revue Scientifique*, July 15, 1882.

Treatment of Genu Valgum.—At the Congress of the German Surgical Society, held in Berlin on June 1, Schede, of Hamburg, read a paper on this subject, in which he mentioned thirty-three cases in which he had performed fracture of the femur, and thirteen similar operations of the tibia for this condition. He thinks the operation is especially suited to children between the ages of two and five years; after about a week the child is able to stand, and in four to eight weeks healing is complete.—*Berliner klin. Woch.*, July 10, 1882.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE, ... $5.00.
SINGLE COPIES, ... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made at the risk of the publishers, by forwarding in REGISTERED letters.

Address, HENRY C. LEA'S SON & CO.,
NOS. 706 & 708 SANSOM STREET,
PHILADELPHIA, PA.

SATURDAY, AUGUST 12, 1882.

THE GRAPHICAL METHOD AS APPLIED TO THE FEET.

IT is often surprising how slowly a good method of study advances. The graphical method of studying the feet was begun thirty years ago, and yet in spite of this and of the brilliant results of Marey, Ludwig, and a host of others, in the use of the same method for other purposes, it is only of late that it has been systematically applied to the investigation of the physiology and pathology of the feet.

The first to appreciate the value of the method were the medico-legal physicians. Hugoulin, as long ago as 1850, used stearin and gelatine to reproduce footprints of the criminal as a means of identification, and though not strictly graphic, yet doubtless it suggested the method which Caussé published, in 1854, in the *Annales d'Hygiène*, and which in principle, though with ingenious modifications, is to-day still the best. One footprint made evidently by a bare and bloody highly arched left foot was found, and there were eight asserted criminals. He smeared the floor with defibrinated blood. Each of the eight prisoners stepped first on the bloody floor with the bare left foot and then on to a brick. Each impression so made was measured by ordinates and abscissæ, and compared with the tell-tale footprint for identification.

In 1872, Duhousset used moist sand in studying the foot-sole of the Kabyles, and in the same year Volkmann, in Pitha and Billroth's *Handbuch*, presented figures of flat feet obtained by transferring the impression of the blackened foot-sole to paper.

But the real systematic graphic study of the feet we owe chiefly to Hilton, Onimus, and Rohmer. Two methods are practicable; the first by tracing the outlines of the foot, the other by obtaining the impression of the sole of the foot.

Hilton, in his *Rest and Pain*, in 1863, attracted especial attention to the outline method. In many cases of disease not only in the foot, but in the various portions of the lower extremity, he observed that the feet were unequally developed, and accordingly with the patient's feet on paper he drew their outlines by a pencil held vertically, and these he reproduced in many places in his admirable book. Sayre, Judson, and others have followed the method, and it is very simple, easy, and, if due care be employed, reasonably accurate.

The other method was established by Onimus in 1876, and he has published several very valuable papers since then, the most recent being in the *Revue de Medecine* for 1881, and in the *Revue de Chirurgie* for last June.

In 1879, Rohmer, in a Thesis for the Doctorate, presented to the Faculty of Nancy, carried the system even further and applied it to the physiology of this portion of the muscular system with not a little success. After dissecting the muscles from the knee nearly to the ankle, just enough to separate them one from another, but not enough to disturb their relations to the bones, sheaths, etc., he first took an impression of the foot-sole in repose; then by traction on one muscle after another, and on groups of muscles such as would be related in normal action or in disease, he was able to show what variations in the impressions of the foot-sole were produced by the muscles, either singly or in groups.

The method adopted by Onimus to obtain the impression is to smoke the paper by a wick soaked in turpentine, being careful not to burn the paper, as that would obscure the results. The patient then treads on the paper, and where the sole has touched it the paper is bared of lamp-black. The impression is then rendered permanent by a fixative applied by an atomizer. Rohmer uses copal varnish; Onimus, "fusian" varnish. We would suggest that collodion and ether would be equally effective and much quicker in drying. Shellac and alcohol also may be used. One point is not to be forgotten, that the figures either of the outlines or the impressions should be reproductions of the figures on the paper and not of the foot-soles themselves, for in the latter case the right and left foot would be reversed to the reader.

The method has been already fruitful in results. Not only has the physiology of the muscles of the leg and foot been elaborated, and to some extent corrected, but paralysis, contractures, arthritis of the ankle and of the different joints of the foot, contusions, and other injuries, have all been shown to affect the forms of the feet very appreciably,

though the disease be at a distance, and sometimes of cerebral origin.

Three types of foot imprint exist. First, the arched foot, consisting of three distinct imprints, the heel, the cushion under the heads of the metatarsal bones, or "anterior heel," as Duchenne has aptly called it, and the toe-tips. Secondly, the flat-foot, in which the entire sole touches the ground, and thirdly, an intermediate, commonest, and best form in which the imprints of the heel and of the metatarsal pad are connected along the outer border of the foot by a narrower or wider line or band. Any one on getting out of a bath and stepping on to dry paper, or a bare floor, can try the method extemporaneously and see to which of the three types his foot belongs.

Possibly also the cutaneous markings on the sole might be studied with advantage. The Chinese, it is asserted, have a "Rogues' Gallery" of the thumb imprints of their criminals. It might be equally valuable to reproduce their foot-soles in a similar way.

THE RESUSCITATION OF THE DROWNED.

AT this season of the year every intelligent person—physician or layman—should be in possession of definite and easily applied information in regard to the best methods of resuscitation of the drowned. Accidents of the sort are so common, and lives are so frequently lost through neglect promptly to resort to approved remedial measures, or, still oftener, are extinguished, when trembling in the balance, by well-meant but rude and harmful endeavors at revival, that the subject becomes one of general interest and importance.

It is, of course, recognized that the primary indication in the treatment of drowning, as in all cases of apnœa, is to procure the free entrance into the air-cells of the lungs of a sufficient quantity of pure air, which shall oxygenate the poisoned blood and re-establish the obstructed pulmonary circulation. It also is beyond dispute that that method of resuscitation is to be preferred which, while applicable under any circumstances and without a moment's delay, enables the operator to expand the chest of the patient to the fullest possible extent, or, in other words, to supply with each movement of respiration the greatest amount of fresh air. In determining, therefore, the particular form of artificial respiration to be selected in such cases, we may begin by discarding all those which depend for their usefulness upon the employment of apparatus, such as bellows, tubes, etc., which are not always immediately procurable, and we are thus reduced to the utilization of various forms of passive movement of the body and limbs of the patient as the only means of attaining the desired object. This, it should always be kept in view, is full expansion of the chest.

The chief methods by which this is effected are more or less familiar, at least by name, to most persons; but it is often astonishing to find in a case of real emergency how little exact knowledge of the subject exists, and how ineffective the efforts at help are apt to be. They may be classified as mouth-to-mouth inflation, manual pressure, the Howard method, the Silvester or "physiological" method, the Marshall Hall method, and the modifications of these known as Pacini's, Bain's, and De Chilly's methods.

The first of these, in which the mouth of the operator is applied to that of the patient, and air forced directly from the lungs of the former into those of the latter, is open to the objection that the amount thus transferred depends largely upon the muscular force and chest capacity of the person supplying it, and that, even if it be sufficient in quantity, it is necessarily loaded with carbonic acid, and, therefore, not well adapted to respiratory purposes. The method of manual pressure, which consists in bearing with some force—not greater than thirty or forty pounds—upon the lower part of the breast-bone and upper and middle part of the abdomen, and then suddenly relaxing the pressure, and which is practically identical with the method known as "Howard's," has been effectual in some cases. Experiment has shown, however, that by this plan not more than twelve or fourteen cubic inches of air can be expelled and readmitted, and that consequently it is inferior to others about to be described. There is danger, too, that, in making the abdominal pressure, food may be forced from the stomach into the pharynx, and subsequently drawn into the air-passages; and this accident has occurred.

The Marshall Hall method consists in turning the body on the side and a little beyond, and then briskly on the face, alternately; each time the body assumes the latter position, gentle but firm pressure being made over the shoulder-blades and the lower ribs posteriorly. The whole amount of air exchanged by this procedure has been found not to exceed fifteen cubic inches, and often to be much less. The method, as described by its author, is also objectionable for the reason that the first movement which is executed is the one of expiration, thus driving out of the lungs what little air they may contain, and losing a few seconds of time, which might be sufficient, in many instances, seriously to influence the result.

The Silvester method is worthy of more detailed description, as equally easy of application with those already mentioned, as open to none of the objections which may be urged against them, and as securing, when employed with a slight modification,

an exchange of from thirty to fifty cubic inches of air with each respiratory movement. Its purpose is to imitate the action of the pectoral and other muscles passing from the chest-walls to the arms and shoulders, which become inspiratory muscles during deep inspiration, and this is effected as follows, the preliminary instructions being applicable to any of the above methods of resuscitation. The patient should be turned on the face, the mouth opened, the tongue grasped with a handkerchief and drawn forward, and the hips slightly elevated. He should be held in this position four or five seconds, or even twice as long, if fluid continues to escape from the mouth or nose. He should then be turned on the back, a roll of clothing, a cushion or some similar support being placed just below the angles of the scapulæ. The tongue should still be drawn forward and retained in that position by an assistant or by a strip of muslin tied around it and beneath the chin. The operator, standing above the head of the patient, should then grasp the arms at the elbows, and draw them directly upwards and outwards until they nearly meet above the head, thus placing on the stretch the pectoral, latissimus, teres, etc., and elevating and rotating the ribs, or, in other words, imitating the action of forced inspiration. The arms should then be immediately turned and replaced at the side. According to the original plan, as proposed by Dr. Silvester, we believe the movement of expiration was then to be imitated by pressing the arms against the side of the chest, but there is good reason for preferring the modification suggested by the Committee of the Royal Medical and Chirurgical Society, who, at this stage, recommend that moderate pressure be made with both hands on the lower part of the breast-bone. This entire process should occupy about five seconds, so that about twelve complete respiratory movements may be made within the minute. The usual mistake is respect to time is that the movements are made too hurriedly, producing an insufficient, panting respiration. While this is being done, hot or cold water may be dashed over the chest, the limbs rubbed from below upward, ammonia held to the nostrils, and hot coffee or brandy given by enema. When respiration is now fairly established, the patient should be wrapped in blankets, kept strictly in the horizontal position, and conveyed to bed, care being taken that, while the warmth of the body is maintained, the air which is breathed shall be cool and pure.

The subsequent treatment consists simply in the cautious administration of food and stimulants, warm milk and brandy, beef-tea, coffee, etc., until strength is re-established.

The methods of Pacini and Bain are peculiar in that the chest is expanded by making traction in an upward direction with the fingers in the axillæ, the only difference between them and the plan just described, being in the application of the force to the upper instead of the lower part of the arms.

De Chilly's method consists in thrusting the fingers beneath the false ribs, and alternately elevating and compressing them, in this way imparting to the general thoracic wall the movements of expansion and contraction. It offers no special advantage.

The prognosis in cases in which complete immersion has occurred for more than two minutes, and the entrance of water into the lungs and the exit of air therefrom have been unimpeded, is exceedingly unfavorable. We know of no authentic instances in which efforts at resuscitation had been successful in such a case. Those instances of recovery after long continuance in the water, of which we frequently hear, will be found on investigation to have taken place under circumstances which permitted an occasional inspiration, a momentary gasp for air which, however insufficient, permitted each time a little oxygenation to take place, and prevented the complete cessation of circulation and respiration.

THE HOMŒOPATHIC TREATMENT OF INSANITY.

At a meeting of the Governor and Council of Massachusetts, on the 19th of July, the subject of providing for the homœopathic treatment of the "State insane" was considered. There were present, also, representatives of the State Board of Health, Lunacy, and Charity. The meeting was held pursuant to a resolution of the Legislature of Massachusetts, which reads as follows: "That the Governor and Council be requested to consider the expediency of providing separate homœopathic treatment of insane persons under the care of the Commonwealth, who shall desire it," etc. The presentation of the homœopathic case was characteristically made by Drs. Talbott and Worcester. The former enlarged on the number of physicians practising on that dogma, and the number of persons who wish to be thus treated. The homœopathists of Massachusetts, he stated, feel so keenly the injustice of being compelled to submit to "allopathic" treatment that they send an insane relation to an asylum only when compelled to do so. But the argument drawn from the number of their adherents and the severity of their prejudice, only prepared the way for the conclusive evidence of the success of the homœopathists in the treatment of insanity. The success attained at Binghampton, had been such, said Dr. Talbot, as to lead to the belief that many are permanently benefited by the mild homœopathic treatment, who would, under other management, have entirely lost their reason. At the Middletown Institution for the "mildly insane," 45 per cent. were cured.

Dr. Worcester followed Dr. Talbot on the same side. He said that the homœopathists regarded insanity as a disease of the body, and their remedies were as useful in this as in any other disease. Dr. Talbot had just before stated that there was no homœopathic remedy for insanity, but for its symptoms, such as sleeplessness, they had remedies which were substituted for bromides, opium, and chloral. Dr. Worcester has lately published a book on insanity, made up of quotations from Bucknill and Tuke, Maudsley, Ray, and other well-known writers. He has merely added some extraordinary matter on the homœopathic treatment, but he does not discard entirely bromides, opium, and chloral. Indeed, he finds himself compelled to depend on them in serious cases. It is perfectly well known to all who have looked into the matter, that these remedies are freely used in these so-called homœopathic institutions. As they have to avail themselves of the literature of scientific neurological medicine, so they make use of, so far as the necessary secrecy will permit, of the medicinal resources of the same. Any results which they may procure from remedial management are thus derived from those sources which they contemptuously style "allopathic." The homœopathic remedies, intercalated, serve to give an appearance of consistency to their practice, and to furnish a basis for statistical statement of results.

Any one having the least acquaintance with statistical methods, will know how figures may be made to support any sort of case. Asylum statistics are especially open to suspicion, when the curative results given are much above the average. The homœopathists had better stick to the "glittering generalities" in which their evidence usually consists. This suggestion we offer because the fine display of figures made by Dr. Talbot awoke no enthusiasm, only suspicion, in the minds of some of the gentlemen present who were familiar with the capabilities of figures and statistics for double dealing. Prof. Edward Hitchcock, of Amherst, a member of the State Board of Health, doubted if they could do any better than the allopaths, but let them try it. Mr. F. B. Sanborn, also a member, seemed to doubt that they could improve on the present method, which does not err on the side of extreme medication, but he expressed a willingness to give their method a trial, the more especially as the increase of insanity demanded additional provision.

If, unfortunately, they are to have the opportunity to test the truth of their pretensions, let it be in the light of day. If they are to have a separate hospital in which to demonstrate the asserted value of their system, their practice must be legitimate, must be a logical outcome of their creed, and must not be aided by the use of other than homœopathic means. Let there be no attempts to secure good results by the application of the present scientific therapy of insanity, whilst a pretended homœopathic system is ostensibly and ostentatiously carried out.

ONE HUNDRED CASES OF NEPHRECTOMY.

IN our issue for March 11th, we considered somewhat fully the subject of nephrectomy, based on an analysis of seventy-six cases. In the *American Journal of the Medical Sciences* for July last, Dr. R. P. Harris, with his characteristic thoroughness and fulness, tabulates all the cases that he has discovered on record, one hundred in number, of which 50 were done in Germany, 24 in England, and 10 in the United States, besides one case under the care of an American surgeon in China.

These recent statistics show that the total mortality is rather more unfavorable than was supposed. Excluding those in which the result was doubtful, we reported 40 recoveries to 33 deaths—a mortality of 45 per cent. Dr. Harris adds 9 recoveries and 12 deaths, so that it stands 49 to 45—a mortality of 48 per cent.—with 6 yet undetermined. Even with this showing, the recoveries from so serious an operation are still over 50 per cent. The lumbar operation, however, has lost its preëminence as to the favorable percentage of recovery. The incision is recorded in 98 cases. Of these, 51 are lumbar and 47 are abdominal. The results are uncertain in 5 lumbar operations (with a probability of 4 recoveries and 1 death); and in 1 abdominal operation, with a probability of death. Not including the uncertain cases, the abdominal incision shows a mortality of 48 per cent., and the lumbar of 43.5 per cent., as against 60 and 36 per cent. of the earlier table. On the whole, it would seem that in cases of doubt the abdominal incision, preferably that of Langenbuch and Thornton, in the *linea semilunaris*, or the long oblique lumbar incision of Czerny, is the best.

THE DURATION OF THE POSSIBILITY OF CONTAGION.

INFORMATION is frequently sought as to how long the risk of contagion in a given case lasts, and the inquiry is commonly made of the doctor: When may a child, who is just recovering from one of the contagious diseases, mingle with the family, and go to school without risk of communicating the disease to his companions? The question has generally been considered to be one more easily asked than definitely answered, and the usual sources of information on such subjects are strangely silent on this. The French Government, through the Minister of Public Instruction, has done a good work in formally submitting the question to the Académie de Médecine, and in another column (page 179) we

publish the answer the Académie has just formulated. This reply is worthy of the widest publicity, and should be placed in the possession of the head of every school and family. If the measures of personal hygiene there defined are faithfully carried out, as they probably will be in France by governmental enactment, our schools and public conveyances will soon cease to be the principal nurseries in which contagious diseases are propagated, and their spread will be in great degree controlled, if the diseases themselves are not largely stamped out.

REVIEWS.

The Immediate Treatment of Fractures of the Leg by Plaster-of-Paris Splints. By John Croft, F.R.C.S. Reprint from the Med.-Chir. Trans., vol. lxiv. Pp. 12. London: 1881.

In a recent editorial The News advocated strongly the use of plaster-of-Paris as a material for the immediate treatment of fractures. No stronger support for the position then taken could be asked for than that afforded by the present paper. Two points only demand especial attention. Mr. Croft does not employ the plaster-of-Paris *bandage*, but *side splints*. Each splint consists of two layers of flannel cut half an inch narrower than the semi-circumference of the limb, the stocking serving as a pattern. Only the outside layer of each splint is thoroughly soaked in the plaster, and then the splints are applied, the dry layer next the limb, and the whole retained in place by a common roller bandage. Of course, traction is maintained till the plaster sets. The ease of partial or complete removal and reapplication, the absence of danger from swelling, the cheapness, and many other reasons, make this form of splint very desirable.

The second point is the result of six years' experience (from 1875 to 1880) at St. Thomas' Hospital, in the treatment of fractures of the leg. In 1875, of 97 simple fractures, 63 were treated by splints only, and 19 by plaster only; in 1877, of 130 cases, 13 by splints only, and 84 by plaster; in 1879 and 1880, 2 and 7 by splints, and 125 and 123 by plaster, out of 130 and 131 cases! Such figures not of one man, but of the entire surgical staff of a large metropolitan hospital, speak volumes for the method. Surely so simple, so cheap, so comfortable, and so effectual a splint, should grow in favor here as there.

Especially would it be found a ready resource in the country, where a full set of splints of all sizes are not often kept on hand, and where good instrument makers are of course inaccessible.

An Index of Surgery, being a Concise Classification of the Main Facts and Theories of Surgery, for the Use of Senior Students and Others. By C. B. Keetley, F.R.C.S., etc. 8vo. pp. 320. New York: William Wood & Co., 1882.

This is a book gotten up in England to help medical students in preparing for their final examinations. The author says it is only intended to serve as a refresher of the memory, and not to stand instead of text-books or lectures. With this object in view, it may be said to be a book likely to be useful. Indeed, it may perhaps help the busy practitioner who has a sudden call to a surgical case, and must run off without opportunity to consult a treatise.

But when this is said, all is said that can be commendatory. The book omits everything about the "*uterus*," while it includes "*rheumatism*." "Castration" is considered, but we cannot find the word "rectocele." Looking as one who refers in haste would, we fail to find anything in regard to fractures of the vertebræ, except that very seldom can any distinction be made between these and dislocations, to which caption reference is made. Then, we find no mention of the use of air- or water-beds.

The make-up of the book is poor. Cheap paper and cheap binding indicate that its publishers do not anticipate for it more than ephemeral reputation.

SOCIETY PROCEEDINGS.

WEST PHILADELPHIA MEDICAL SOCIETY.

Stated Meeting, July 3, 1882.

S. S. Stryker, M.D., President, in the Chair.

Treatment of Summer Complaints in Children.—Dr. Wm. D. Ronaldson, in opening the discussion, spoke of the frequency and causes of entero-colitis, dwelling especially on the influence of heat and improper food. He also called attention to the fact that the disease is situated chiefly in the large intestine. Entero-colitis is, he said, more properly to be considered "summer complaint" than is cholera infantum.

The treatment he described was that of the books: oil, rhubarb, opium, colomel, powdered crabs' eyes, acetate of lead, nitrate of silver, and the vegetable astringents. Warm applications, tonics, and stimulants were also mentioned. Dr. Rohrer, of Zurich, was quoted as advocating very strongly the use of coto and its preparations, and Dr. H. C. Wood as advising the application of cold as for heat-stroke.

Dr. T. A. Downs said one of the most important features of cholera infantum is the constant vomiting. For this he thought the use of calomel, in doses of one-sixth of a grain, combined with three-quarters of a grain of bismuth, given every hour or two, to be the best remedy. He had also noticed that the serous discharges, which are so free and so great, were controlled by small doses of the fluid extract of ergot. This remedy is supposed to influence the nerves which preside over the circulation, and acts through that system. With these two remedies, and a little laudanum or paregoric to control the bowels, and occasional wet packs to bring the skin into proper activity and perhaps cause some elimination, he generally manages to get good results. He thought stimulants play a very important part in the treatment of summer complaints.

Dr. R. M. McClellan said he thought the cause of cholera infantum could be set down in 19 cases out of 20 to improper feeding, and, most of all, to the nursing-bottle. This is a difficulty which is very hard to overcome. If any one is so unfortunate as to have to raise a child by the bottle, he learns that it is almost impossible to keep a bottle sweet and clean. Even if kept constantly immersed under soda solution, it will get sour. He thought the habit of using the nursing-bottle should be discouraged, and drinking from an open vessel substituted. It is surprising how young an infant can be taught to drink from a vessel with a straight edge, like a wine-glass, when it will absolutely turn away from a spoon. When the wine-glass has been used, it is not hard to get the child to use a larger vessel, like a tumbler or cup. In this way the times of feeding can be well regulated also. There is no habit worse for an infant than to pull away at a bottle by the hour—for the convenience of the mother or nurse.

In regard to medication, he got the best results from

a combination of subnitrate of bismuth with opium; such a combination as one grain of subnitrate of bismuth with an eighth of a grain of Dover's powder.

For food, he thinks Bermuda arrowroot very valuable. It must be carefully prepared, so as to be thoroughly cooked, and not raw. All the white particles must disappear and leave a clear bluish-white homogeneous mass, like clear-starch. This may be mixed with an equal quantity of cooked milk and flavored slightly with sugar and perhaps a little nutmeg. The good effect of using arrowroot came under his notice in the army, where it cured many cases of camp dysentery when other methods failed. In using it for cholera infantum, the child must be restricted to it, and not allowed to branch off into other articles of food, which might interfere with the good it would accomplish.

For extreme prostration and vomiting, he uses fine, scraped beef: scraping the beef with a dull tableknife, and giving, of the pulp thus expressed, morsels the size of a shelled pea.

The child must be kept in the open air as much as possible, and excursions upon the water made as frequently as may be. The child must not be unnecessarily disturbed. Every movement causes pain, and bouncing on the knee is a cruel practice. He thought the popular plan of excursions upon the water owes a good deal of its advantage to the easy motion of boats, as compared with vehicles on land.

Dr. Henry Mullen said he formerly used castor oil and laudanum; but of late he relied chiefly on stimulants, with bismuth and pepsin in small doses, and, if possible, getting the child into the open air and away from the city. He does not like sending children to the country, but knew no child that was sent to Atlantic City or Cape May, in reasonable time, that did not get well. For the vomiting he uses calomel. If this does not control it, he finds creasote of great advantage.

Dr. Charles W. Dulles then described the method of irrigating the large intestine, practised by Monti, of Vienna, and cited some cases to show its applicability to the treatment of cholera infantum. He laid stress upon making a distinction between an injection and an irrigation, and said he believed that by soothing and cooling and supplying water to the system, this method would prove of value not only in inflammations of the large intestine but also in those of the small one. He advised in the acute inflammatory stage the use of cool water; but in chronic and low inflammatory condition the use of warm water.

Dr. James H. Lloyd questioned the feasibility of irrigation, because, in his experience, the lower bowel so quickly discharged the fluid injected. With regard to arrowroot, he said he used it with a much larger quantity of a mixture of equal parts of milk and water. The arrowroot is meant to act mechanically and to prevent the formation of too hard a curd. He has seen the very best results from the use of the gelatine formula given by Meigs and Pepper—better than from any other diet.

Dr. R. M. Girvin said he had long held the view that in these diseases infants die more from the influence of the heat of summer than from any other cause. An adult can help to make himself cooler, but a child cannot do this. With this view he thinks a very important part of the treatment of cholera infantum must consist in the application of cold, just as is the case in sunstroke. He has an idea for the summer, of having relays of large rubber bags to contain cool water, which when applied to a child will reduce its temperature more comfortably than the cold pack.

One of the greatest difficulties we meet in these cases is the question of artificial foods. It is a very grave question, and one we cannot battle with, so long as we have to deal with men who supply them only for the purpose of making money—from the man who delivers sour milk at the door to the man who displays artificial foods and meats with fancy names in the drug stores. The trouble with the artificial foods is that they consist of starch and not gluten. The starch is rapidly converted into glucose and proves irritant.

When we turn to cow's milk we find that it sours and forms a hard curd, the casein coagulating in masses, too large and too hard for an infant to digest. This can only be corrected by adding something which will prevent such coagulation, and make it more like that of human milk, which coagulates in flakes and small particles. Very few children ever die of cholera infantum who have a full breast of human milk to nurse. No doubt it is right to make war upon the nursing-bottle; but he doubted if we shall ever be able to do away with it.

As regards the therapeutics of cholera infantum, he had found that his practice varied with different cases. He had had much benefit from the use of the oleaginous prepartions. The old combination of castor oil with laudanum and cinnamon, he had found very useful. He has not had the good results from the use of calomel which many others have, though when vomiting depends upon some irritant in the alimentary canal, to empty the bowels with calomel often serves very well.

His use of astringents, he said, was small, but he made frequent use of alkalies.

The beneficial influence of stimulants he did not think could well be over-estimated. Good brandy must be our sheet-anchor. Ten to thirty drops can be given every two hours.

He had never used irrigation, but Dr. Ellerslie Wallace, as is well known, thinks no treatment is so good as injections of sulphate of zinc.

Dr. J. B. H. Gittings said he had very satisfactory results from the use of calomel and Dover's powder. He starts with castor oil and a little laudanum, giving one or two doses, and follows them with minute doses of calomel and Dover's powder. He uses calomel $\frac{1}{12}$th grain, Dover's powder $\frac{1}{6}$th grain, and sugar 1 grain, every two hours till the stools are green. The stools soon become green and yellow, and then green, yellow, and brown; and, without discontinuing the medicine, the green will altogether disappear. He uses brandy also.

For sick stomach he thinks very highly of a plan of his father's. This consists in steeping a handful of green peach-tree leaves in a goblet of cold water, and giving, within half an hour and onward, a teaspoonful every two or three hours. He has also found this remedy very good in the vomiting of bilious fever in adults. He had experimented with hydrocyanic acid, but did not get the same results that the infusion of peach-leaves secured. He finds spice plasters valuable also.

Dr. John H. Musser had treated cholera infantum in Blockley Hospital with cold baths and ice bladders, and cold cloths, securing quiet, reducing the temperature, and checking the diarrhœa. The use of cold and stimulants he thought better than any other plan of treatment. The high temperature has a baleful influence on the nervous system, and the correction of this does great good to the patient. It is undecided whether the use of alcohol in the first stage does not do good by its antipyretic effect. Of course, in the stage of collapse it acts as a stimulant. There is often little evidence seen at an autopsy of inflammation of the bowels. In a case in which he made a careful examination with Dr. John Guitéras in Blockley Hospital, they found no lesions whatever in the entire gastro-intestinal tract, but rather an anæmia of the whole mucous membrane.

In entero-colitis he has gotten the best results from the use of castor oil and rhubarb, or rhubarb and magnesia,

given for twelve or twenty-four hours till the tormina and tenesmus are relieved, and followed up with astringents. He has seen creasote also do good, and quinia. Ringer recommends doses of $\frac{1}{100}$ of a grain of corrosive sublimate. This he had never found of use. One of the best astringents for simple diarrhœa is aromatic sulphuric acid. In regard to arrowroot, he cited a case to show the importance of getting it pure.

Dr. Michael Lampen has used calomel but little, and not with much satisfaction; bismuth he uses generally, and with success. He has often found barley-water of great service when nothing else would agree with the child.

Dr. R. M. Girvin again dwelt upon the important *rôle* played by heat in this disease. He believed the bowel trouble to be secondary and a result, but the application of water to it ought to be grateful to the child. At the beginning of cholera infantum he uses a combination consisting of castor oil two parts, aromatic syrup of rhubarb one part, and a few drops of laudanum.

He uses a modified spice plaster, consisting of paregoric one part, Jamaica ginger one part, and hot water two parts, in which a cloth is steeped and laid upon the child's abdomen. This can be diluted if too strong for the infant's skin.

As to the influence of malaria in this disorder, he believed it was over-rated. In regard to the use of aromatic sulphuric acid, he said we sometimes forget that babies may have the same cravings for acids as adults have. He often gives dilute sulphuric acid.

As an astringent, he finds acetate of lead and morphia very valuable. The formula must be carefully prepared by the druggist; so as not to overdose with morphia. A good prescription is:

℞. Plumbi acetatis, ... gr. v.
Morphiæ sulphatis, . . . gr. $\frac{1}{10}$.
Misce et div. in Chart. No. x. (or xij).

Barley, rice, and toast water are good to prevent the solid coagulation of casein, and are good to mix with condensed milk. A good way to make barley-water is to have the grains crushed in the house, boiled and strained through a thick cloth.

Dr. John H. Musser thought irrigation did good by cooling and supplying water to the thirsty system. He had seen good results from using minute doses of chloral to quiet the restlessness. He referred to the treatment by salicylate of calcium which Dr. Wm. C. Dixon had recently brought before the Society, as promising most excellent results.

Dr. S. S. Stryker said many of his ideas had already been expressed. He would add that it was his custom to give large draughts of water. It is sometimes objected to this that the child vomits it. But it will vomit, whether you do this or not, and some of the water is taken up too quickly to be vomited.

The combination of aromatic sulphuric acid with nux vomica and a little laudanum he found very valuable as a tonic toward the end of the treatment. For stimulation he prefers burnt brandy, made by putting some brandy in a saucer, adding a lump of sugar, and setting it on fire. He also uses the fine cordials—Maraschino and Curaçoa—which do good, and are very acceptable. He is also accustomed to use injections of flaxseed tea, to soothe the bowel and allow its irritation to subside.

Dr. W. D. Ronaldson, in closing the discussion, went over some of the ideas advanced by others. He said that his experience was that powdered crab's eyes act better than prepared chalk; he could not say why. *Apropos* of the use of infusion of peach leaves, as suggested by Dr. Gittings, he said that he had found that cold infusion of slices of apple would sometimes stop the vomiting in very severe cases of dyspepsia.

Some of the speakers had objected to speaking of cholera infantum and entero-colitis together. As a fact, in the summer complaints of children, there are ten or twelve cases of entero-colitis to one of cholera infantum; and, besides, no matter what might cause an attack of summer diarrhœa in an infant, if it became chronic, it always became an entero-colitis.

Résumé by the Reporter.—In this discussion all the speakers agreed that the food of an infant suffering with summer complaint should consist of good breast milk if possible, and, in the absence of this, of the purest cow's milk, diluted with starchy and gelatinous preparations. One speaker advocated teaching a baby to drink from a straight-edged vessel, so as to avoid the impurities of the bottle. Fresh air, seashore air, excursions by water, bodily rest, large draughts of water, large injections of flaxseed tea, irrigation of the colon, and external application of cold, by cloths and baths, were recommended.

The medicinal treatment approved of was such as would first remove any irritant from the bowels and then quiet them—castor oil and rhubarb, or rhubarb and magnesia, or calomel in small doses, with a very small quantity of opium (in Dover's powder), until the bowels were cleaned out. For the diarrhœa, if persistent, bismuth, pepsin, Dover's powder, laudanum, paregoric, morphia, acetate of lead, and aromatic sulphuric acid were recommended. The combination most used seemed to be about a grain of bismuth with about one-eighth of a grain of Dover's powder, or about a twelfth to a sixth of a grain of calomel with a sixth of a grain of Dover's powder. There was one recommendation of small doses of fluid extract of ergot.

For the vomiting, calomel, creasote, minute doses of chloral, large draughts of cool water, and the use of teaspoonful doses of a cold infusion of peach leaves were recommended.

Stimulants by the mouth and the application of spices to the skin of the abdomen were also approved, as well as the use of scraped beef and nux vomica, aromatic sulphuric acid, and laudanum during convalescence.

CORRESPONDENCE.

LETTER FROM BERLIN.

The Bacillus Tuberculosis—The Gelatine Culture Substance: Preparation and Use—Blood as its Soil, and the Use of the Color-tests in its Recognition.

Of all the materials tried to secure the so-called *rein cultur* (literally pure culture, *i. e.*, the isolation of parasitic forms), but three seem to be now in use in the mycological department of the Gesundheits-Amt: to-wit, the potato, the gelatine, and the blood-serum preparation.

Perhaps nothing would better indicate the patience and persistence, I might almost say obstinacy, with which Dr. Koch has worked, than the citation of the various substances used and rejected as unfit soils for the growth or sustentation of individual germs. Each form or family of parasite requires or develops best in a particular soil, and the discovery of the particular soil best suited for each form is the object chiefly aimed at; for when the proper culture substance has once been found, a constant supply of bacilli, bacteria, or micrococci productive of a special train of symptoms, or disease, is always at hand for demonstrative purposes or for experimentation in a new direction. Test tubes bristle about the room, as I have already said, each properly labelled as to its contents, and from these tubes pretty much every day matter is taken for inoculative purposes. For instance, yesterday it was found that the gelatine culture substance containing

the milzbrand (anthrax) bacilli had become impure, that is, that it contained also other bacilli and some micrococci foreign to milzbrand. The discovery was made by removing a minute particle and examining it under the microscope. It had become impure by frequent removal of the sterilized cotton plug for former experimentation. It was therefore necessary to have a pure supply. So far as could be seen by the naked eye, there was no impurity; but nothing can be seen by the naked eye, except an appearance of mould, vegetable mould, just as we see it upon moist bricks or cellar walls. The microscope, however, revealed the impurity at a glance. Now the mouse is singularly susceptible to the poison of milzbrand, that is, the mouse offers a singularly fertile soil for the growth of the milzbrand bacilli. It seems to have a sort of selective affinity for it, so that even if an impure material be inoculated, the animal invariably dies on the next day. All its organs, its blood especially, teem with milzbrand bacilli pure. So on this occasion, the test tube was held upside down in the left hand, the platinum wire (inserted into a glass rod for a handle) bent into an eye (like that of a needle), or as we would say a hook, held in the right-hand, is carried up into the "mould"-looking substance and a minute, barely visible portion is brought away. This portion or fragment is put upon a cover glass, previously sterilized by heat in an iron chamber over a Bunsen's jet, and is in turn covered by another cover glass likewise sterilized. The two cover glasses are now drawn across each other in order to get the thinnest possible layer of the "mould." It looks indeed now only a film, just as if blown upon by the breath. The cover-glass is now pressed upon an object glass, likewise just sterilized, and is then examined. The characteristic bacilli are displayed in myriads; on this occasion, *verunreinigt*, contaminated, as stated, with other micro-organisms. Thereupon, a fresh fragment is removed for inoculation purpose to get a fresh, pure supply. A glass jar covered with a wire grating is now brought into the room. The glass jar contains a white mouse in perfect health. The grating on top of the jar is substituted by a small piece of board, which does not quite cover the mouth of the jar. A long forceps is inserted by the side of the board into the jar and the mouse is caught by the tail and carried up to the top of the jar, so that the tail is completely out of it and the body of the mouse is wholly in it. With a pair of scissors a little hair is cut away from the dorsal surface of the root of the tail, with a knife a small incision is made, and a little pocket of skin dissected up into which the platinum point or eye is carried. It is the work of about two minutes, the whole procedure from beginning to end. On the next day, without a single exception as yet, the mouse dies. So to-day, the dead mouse is brought into the room stretched out by an assistant upon a board. The experimenter cuts through the skin by a long sweep from the throat to the pubes, and dissects it back on each side, because no hair, which carries so many *pilze* of all kinds, must touch the interior of the body. Now the abdomen is opened with a pair of scissors (knife and scissors just previously heated to redness and allowed to cool), and the thorax is cut away just as in a post-mortem examination. With a lance (also just heated) the right auricle is entered and the drop of blood upon its end is examined under the microscope as before. It is found swarming with milzbrand bacilli, pure. The platinum wire is now carried into the right auricle, and is then inserted in a test tube half filled with sterilized gelatine, inserted by punctures or penetrations which reach half-way down the tube. The sterilized cotton plug is re-introduced, and the tube is marked with its "etiquette" (label) and put away. By the next day, or in two days, the "mould" begins to grow, and at any time a fragment may be removed for fresh examination or experimentation.

Fresh gelatine culture fluid was made in quantity a few days ago, and I witnessed the process from beginning to end with a view, and with permission, to write it out. It is called "sterilized gelatine bouillon," and is made as follows:

Beef (lean), 500 grammes, is thoroughly minced with water, 505 grammes, and left standing over night in an ice-chest. On the next morning the mixture is filtered through muslin, the residue being subjected to pressure. The filtered fluid is now boiled until it becomes perfectly clear, the process requiring about one hour. It is now filtered through muslin again, and is then diluted with distilled water to 500 cubic centimetres. There is now added to it peptone-siccum, 10 grammes, and common salt 5 grammes. The mixture is now boiled again. This fluid constitutes the peptone-bouillon. We might call it number one.

Now pure gelatine, 30 (in summer 40) grammes, is left standing about one hour in pure water, 500 grammes, whereby the gelatine becomes perfectly soft. It is then warmed gently in a water-bath until the gelatine is entirely dissolved. This constitutes the gelatine fluid number two.

The two fluids are now mixed together and neutralized by a concentrated solution of sodium phosphate (whereby is a deposit). The neutralization is tested with both litmus and curcuma. The mixture is now filtered into a well-sterilized glass vessel, closed with cotton and boiled again, this time again in a water-bath. So soon as it cools the gelatine thickens. It has now the color of amber and the clarity of yellow stained glass.

The sterilized gelatine culture substance is not yet quite ready for use. It is withdrawn by sterilized pipettes into sterilized test-tubes, plugged with sterilized cotton. But though there is no question of the presence of developed bacteria, there may still be germs of bacteria which resist a high degree of heat. If such germs be present, however, they will soon reveal themselves as opacities in the clear amber jelly, and, if left alone, they would soon ruin the culture substance. So soon as they are seen, however, and even if they are not seen, the precaution is taken to kill them by gently boiling the gelatine (test-tubes with cotton plug in a water-bath) for a few minutes. This operation is repeated for several successive days, when the gelatine is finally absolutely sterilized, as is proven by the fact that it keeps, like the sterilized potato before described, for months or years (if the cotton plug be not removed) without revealing opacities denoting the presence of germs.

Of course, all these preparations are now made by competent assistants—servants, so that the experimenters find everything ready for work. Care must be taken not to boil the gelatine fluid too much or too many times, else it loses the property of gelatinization, when it would have no advantage over a fluid culture substance.

In the study of the germs of drinking water, of the soil, or of the air, the gelatine is gently warmed to a fluid or semi-fluid state, withdrawn by a pipette, and allowed to flow over a number of object glass slides previously sterilized in the hot air-chamber. It must not flow out to the edges of the slide. It soon sets upon the slide, and may then be inoculated with water or air germs, or, exposed to the air for an hour or so, be allowed to collect the air germs. The slides, four or five in number, are placed upon little glass banks or benches under sterilized glass globes (as in the potato observations before described) and individual opacities, as they grow, are removed from time to time and examined under the microscope for their exact nature.

Of course, contamination is likely to occur with each removal of the glass globe for examination purposes, but the contamination will remain fixed where it falls, of course, and cannot ruin the whole surface of the gelatine, or affect all the particular parasites peculiar to the water or soil. This is, of course, the preëminent advantage of the solid culture substance, and is the easy explanation of the wonderful results already secured.

But the tubercle parasite is not grown in the gelatine culture substance. Each parasite has its own soil, like the vegetable world of larger growth. The soil of the tubercle parasite is blood, and the discovery of the fact that for the tubercle bacillus, which will only show itself in colors, but was made to show itself in this way, clear and distinct and beyond a shadow of doubt, the discovery of the fact that for this bacillus its own soil could be made so clear that any one can see it grow in it, is, I take it, the greatest revelation of modern times.

In the study of the etiology of tuberculosis, Koch soon found that neither the potato nor the gelatine-bouillon were suitable soils for the cultivation of its principle. His researches with anthrax had long since made him familiar with the best soil for its bacilli, and with the fact that some animals are peculiarly susceptible to it, while others enjoy more or less immunity against it. Mice, as we have seen, are so singularly susceptible to it that the body of the mouse is used as kind of filter or sieve to separate it from other micro-organisms. On the other hand, rats are not attacked by it at all. Neither do earth worms suffer from it, nor do they even act as carriers of it. It is well remembered the sensation which Pasteur lately excited by declaring that earth worms carry this poison from the depths of the earth in which animals dead of it are buried, to the surface to infect living animals. The story was regarded as one of the proofs that fact is stranger than fiction. Koch conclusively demonstrated the falsity of this conception with a chain of experiments that may serve as models for like investigations. He buried animals dead of it in the earth, and filled the earth with worms. These worms he extracted from time to time, cut them up in small pieces and examined them for bacilli, which he never found. Next he injected the contents of the earth worms into mice without effect, making always a control experiment of injecting some of the earth into other mice, which were always killed by the germs which it contained. Next he proved that the bacilli cannot live at the low temperature of the deeper regions at which animals are buried, and lastly, he showed that this earth-worm explanation was entirely superfluous, anyhow, for the bacilli themselves are voided with the bloody urine that escapes before death, and with the bloody discharges from the nose, etc. Voided with it, they are able to live and develop for a time upon the nutrition afforded by the earth itself, and may be liable to be washed off by floods to great distances, where they overspread meadows and thus reproduce the disease. In the work in which this refutation is published Koch claims that Pasteur has proved nothing new of this disease, that he has not acknowledged the work of his predecessors, and that his conclusions only tend to confuse and perplex the facts that are already thoroughly known. He entertains a high opinion of the geniality and ingenuity of the French observer, but believes that his conclusions will be entirely forgotten in a decade of years.

But this is aside from the subject of tuberculosis, which is the text of this letter. It would seem to be a very natural thought to select blood as the test medium for the cultivation of its "virus," as it used to be called, but the problem was not how to solidify it, for that occurred naturally enough in the process of coagulation, but how to get it clear. How long and how persistently this task was worked at it would be hard to say, but the end was finally reached, and now it seems easy enough, For the proof of the existence of a bacillus peculiar to tuberculosis could not be considered complete without the ability to propagate the disease with it. Now, Koch had satisfied himself that he had discovered the bacillus with his color-tests. He saw this particular form recur again and again, with such frequent repetition, a form so totally different from the other familiar forms as to soon convince him of its import. But to put the proof beyond dispute it was necessary to be able to cultivate it by itself, apart from every other form of micro-organism, and to effect this object it was necessary to have a suitable solid culture substance. This soil or substance was finally found, as stated, in blood. Vials, or test-tubes, of it now stand about with the bacillus tuberculosis growing in it, some of them nearly a year old, some prepared but a few days ago, so that at any time, and every day the experiment is made, new inoculations can be done, and the blood is prepared as follows:

A glass vessel, beaker, or jar, is sterilized by steam, and into it is received, directly from the body of the sheep, a quantity of blood. The vessel is now simply covered and in no way touched, above all things, is not moved, that the process of coagulation may quietly proceed. Agitation of the vessel would prevent or retard coagulation; touching it might contaminate it. Thus, then, it stands absolutely still for from twelve to twenty-four hours. A glass pipette with a bulb in its centre is now sterilized by being heated to redness, and through it the supernatant serum is withdrawn, and emptied into sterilized test-tubes, closed with a sterilized cotton plug. The test tubes have been previously sterilized in an air-bath of 150° to 180° C. The test-tubes having now been filled, strictly speaking, about one-third full, with the serum, are put into a water-bath at 58° C., where they remain for an hour. This process is repeated once a day for six days, the sterilized cotton plug being never removed.

This is the process of sterilization and now comes the process of gelatinization. To effect this purpose, the test tubes are put into a water bath again. This time they are all inclined somewhat, so as to lie sideways, about at an angle of 45°. Of course, the exact angle of inclination is immaterial, but I should like to convey the correct impression. They are inclined sideways so that when the blood serum "sets," it will lie partly along the side of the tube, where a greater surface is offered for inspection. In this position in the water bath they are subjected to a heat of 65° C. This degree is very material, for long experience has taught the exact amount of heat that may be employed to secure the desired result. For instance, if the temperature ran up to 75° C., the serum becomes opaque; at 65° C., not sustained too long, the serum coagulates to a solid or semi-solid mass having the color of amber, and about the clarity of some of its varieties. It is never so transparent as the gelatine-bouillon preparation, but is more than translucent, as denser opacities may easily be detected in it. The exact length of time occupied in the process of gelatinization cannot be given. It is necessary to lift the test tubes out from time to time, to see when coagulation or gelatinization has occurred.

The blood-serum soil is now ready for use. A test tube may be directly inoculated, by the process already described for sputum, or from the formerly so-called "virus" taken from a tuberculous lung, or better, perhaps, from the tuberculous products of an animal killed in the height of the disease. At first, nothing is seen in the test tubes, but in about forty-eight hours, a little

scaly appearance presents upon the surface, different from the "bloom" of milzbrand or septicæmia, and this scaly product grows very slowly, until the whole surface or a larger part of the upper layers of the serum is filled with the tuberculous "matter." This matter when now removed by the platinum wire and examined under the microscope is seen to consist of, as the Germans say, "*lauter*" bacilli.

I have gone minutely, or perhaps tediously, into the description of these processes, but I am justified in it, I think, by the failures which occur with the beginner in this field of work for want of a few details. Here, I repeat it, all these preliminaries are prepared by competent assistants, and the experimenters find the tubes all properly filled and labelled, standing in racks and ready for use.

As I have already, in previous letters, given a full description of the methods of inoculation, hypodermic injection, etc., I will now proceed to the color tests, by the use of which any one may detect the bacilli for himself in any of the products of the disease. These tests have, of course, all been mentioned by their author, else I should not mention them at all, but not with that fulness, perhaps, which the new worker requires. The old skilled microscopists and pathologists, who are familiar with the methods of using color tests, and who are already, for aught I know, working up the subject in full practical use, will excuse the prolixity with which details must be mentioned to be of any service to the neophyte. And here, I may say, I am speaking from failures in personal experience with the bacilli of tuberculosis. Methods will doubtless soon be simplified to such extent that any one may detect bacilli in a few minutes, but that is not the case as yet. It takes a good hour now to give an opinion that is positive. But this opinion can be positive, I am prepared to declare.

We will suppose that a specimen of sputa is brought in, as it is here every day, for examination. Nothing else is known about the case, nor is anything else cared about it, any more than any history is cared about when a piece of ham is brought in to be examined for trichinæ. The specimens come in here in glass vessels, in one of which we will let our specimen stand.

This is no place or time to go into a history of the color tests. Microscopists have known the value of these tests in histology and pathology long ago. In this particular field, mycology, we may as well call it, it has also long been known that different bacteria could be colored in different ways; some tests in one way, some in another; indeed, it was proposed long ago to distinguish different forms by their affinity for certain colors. Koch makes a better distinction in adding to the color reactions, the kind of soil in which they will grow. With what a variety of colors Koch has worked, his colaborers in this field of etiology fully know. For our purpose here it will be enough to state that the principal colors now in use are methyl violet, methylene blue, fuchsine (red), gentian, Bismarck brown, and vesuvin (brown). All these colors can be readily obtained of any good chemist here, and doubtless many of them have been used by the microscopists at home.

Milzbrand bacilli are best studied, or best seen, with the blue color of the methylene blue, and it was probably from his extensive studies in this field that Koch was led to use this color most in his work upon tuberculosis. I say probable from lack of any definite knowledge, as one does not like to seem too curious in inquiring into causes or incentives. But no one, not even Koch, would have even discovered the bacillus of tuberculosis by the use of any one color. And this is the evidence of the persistence and patience (qualities whose use when crowned with results, the world calls genius) of this particular student. He made experiment upon experiment, at last, among others, with a brown color superimposed upon the blue, when there began to recur with the use of these colors, a form of parasite never seen before, and requiring additional study. So about, as nearly as I can gather from conversations which go on about me, was this bacillus of tuberculosis worked out, and then implanted and fixed, I might say, in its own nutrient soil.

Koch worked out the parasite peculiar to tubercle, first with methylene blue and vesuvin, successively, but by no means immediately successively, or without intervening steps employed.

The following is, then, the aniline coloring solution first employed:

1. Distilled water (sterilized by long boiling), 200 grammes.

2. Concentrated alcoholic aniline coloring matter (methyl violet, methylene blue, fuchsine, chrysaniline yellow, or aniline green—no matter which, the blue mostly), 2 grammes.

Mix and make alkaline by adding one-tenth cubic centimetre of a ten per cent. potash solution.

This constitutes the alkaline aniline coloring solution, which was employed as the first color up to a few months ago.

The only objection to it was the fact that the preparation must remain in it for a long time, twenty to twenty-four hours, before it is thoroughly impregnated with the color. True, the time could be shortened to one hour, or even half an hour, by heating it in a water-bath at 40° C., but this added another step to the examination, already somewhat complicated. So that for quick work, the modification lately introduced by Ehrlich, has been substituted, and is now mostly in use.

Ehrlich suggested, and was the first to employ, so Dr. Koch says, the use of an aqueous solution of aniline oil, to which the coloring matter is directly added. The aqueous solution of aniline oil has the advantage of being already alkaline, so that two steps of the process, namely the subjection to heat, and the alkalinization may now be dispensed with.

He will assume that the first color has now been prepared and is standing in a bottle ready for use.

Four or five watch-glasses are now half filled with the coloring matter, and left standing upon the table.

Now from the glass containing the sputum, a minute fragment (from anywhere, though the whitish caseous-looking masses in phthisical sputum are "*lauter*" bacilli) is removed with the ever useful platinum hook or wire previously "*ausgeglüht*" (which is the work of a second or two in a Bunsen's jet, which is always burning on the table), and is not put, but spread in a thin, almost invisible, film over the whole surface of a *cover* glass. And now, and here, comes in a delicate point. The sputum must be fixed upon the glass. If not, the alcohol in the color tests will throw down a precipitate, which precipitate many and many a "bacteria fanatic" has taken for a special form. The specimen or "*preparat*" is very simply fixed by heat. To get this point exactly was a nice and delicate thing. If not heated enough, the precipitate forms; if too much, the specimen is burned up, destroyed. "Pass it three times through the flame, thus," is the word. Some of the workers hold it between the forefinger and thumb, others by the edge or cover with a forceps, and pass it slowly through; about as one would pass the finger through the flame of a candle, not to let it burn; and thus the specimen is fixed. In skilful hands this fixation requires about ten seconds.

Now, then, the object glasses, object side down, are dropped upon the surface of the coloring matter in the watch glasses where they must float and not sink, else the color will not reach the specimen lying in the bot-

tom of, and in close apposition with, the glass. *Here the specimens must lie for half an hour.*

While they lie taking up the color, violet we will say, because that is the best for quick work, we may proceed to prepare the second color. Both colors—I might say all colors—are already prepared here by the assistants, but our laboratory is not yet thus provided.

The second color is vesuvin, which is brown, and it is very easily made. It is simply a concentrated *aqueous* solution, and it stands upon the table, not with a cork, but with a small glass funnel in its mouth, lined with filtering paper. For the vesuvin must be filtered always immediately before using. This looks like another complication, but is not in reality, as a little of the fluid in the bottle is simply poured into the funnel, and, as it drops, it is let fall upon the "*preparat.*"

But not yet. The half hour in the violet coloring matter solution has now elapsed, we will say; the object glass is picked up by the cover with a pair of forceps, *and is decolorized!* The truth is, it is not all quite decolorized, for the tubercle bacilli will not quite let go of all the coloring matter. The object is to decolorize everything else, any other bacteria, for instance; with manifold forms of which all sputum teems, all cell formation, in fact, everything else.

The decolorization is very quickly done. On the table there stands a small glass vessel two-thirds filled with a solution of concentrated nitric acid (Ph. G.) one volume, and distilled water ten volumes.

The cover glass (*preparat*), held by the forceps, is now dipped into this decolorizing solution, and gently moved about two or three times (in five seconds perhaps) until, as is seen by the naked eye, all or nearly all the color is gone

Next, the nitric acid is washed off by being held for a moment under a small stream flowing from the hydrant.

Now, then, the funnel is lifted from the vesuvin bottle, and two or three drops of the thick deep brown fluid is let fall upon the specimen, which is tipped about from side to side that the color may pass over the whole surface of the glass. This takes about five seconds more. Superfluous vesuvin is shaken off, the cover glass is put and pressed down upon a clean object glass, and is examined for bacilli. If any are there, if only one is there, it stands out perfectly sharp and distinct, a violet rod in a brown field, unmistakable in its form, *in its color*, from anything else. Perhaps not even one may be found in this specimen. Then other specimens, prepared at the same time lying in the first color, are successively picked up and examined. If any are found in any of the specimens, the diagnosis of tuberculosis is absolute, just as it would be in the case of one trichina in trichinosis; but the absence of any would not necessarily exclude tuberculosis, just as would be the case in trichinosis.

The secret of the discovery lies in the fact that the original color imparted to the tubercle bacillus is not yielded up, while it is yielded up by every other bacillus, except that of lepra, which conducts itself just like this bacillus, though it is very different in its form. Any confusion of these diseases is not likely to occur with us, anyhow, so that this resemblance has no practical importance.

Mostly, the specimens teem with bacilli, which are recognizable at the first glance.

The specimen may be conserved in the usual way with Canada balsam, but it is important to know that *the color fades out in about two months.* It may be restored, of course, by beginning *de novo*, after careful recovery of the specimen from its bed of balsam with turpentine in the usual way.

Some one asked Dr. Koch, the other day, why he did not prepare and sell the specimens, and thus realize a small fortune. He would consider such a work unworthy the dignity of a science, he said, but even if he had not been restrained by any such feelings, he would have rendered himself liable to the charge of imposture, he added, with a smile, after the color of the specimen had faded out.

To my very great regret, but perhaps to the equally great pleasure of many of your readers, I am compelled to leave Berlin. I have still some notes that might be of interest; at any rate, I may have the opportunity of informing you of the reception of the bacillus tuberculosis elsewhere than in Berlin.

J. T. W.

Berlin, July 4, 1882.

POISONOUS EFFECTS OF SALIVA.

To the Editor of The Medical News.

Dear Sir: I would be greatly indebted to you if you would insert in your columns some exceptions, which I beg leave to take, to the statements made by Dr. George W. Sternberg, U.S.A., in your issue of July 8, 1882.

Owing to an accident, the current numbers of The Medical News did not reach me until lately, and I was entirely unaware that my remarks, made before the meeting of the West Philadelphia Medical Society and printed in The Medical News of May 27th, had been published in that or any other journal; nor was I aware of the letters of Drs. Sternberg and Claxton until my attention was called to them.

My surprise was great, to learn that I had, without forethought or reason, excited the indignation of such an esteemed friend and distinguished experimentalist as Dr. Sternberg, for my remarks, even though incorrectly quoted in the columns of the News, do not, I think, assail him or the character of the work done by him. Nevertheless, had what I said at the meeting been literally quoted, and had Dr. Sternberg stated his objections more accurately, this discussion, which is at once unpleasant and unnecessary, could have been avoided.

Dr. Sternberg says in the letter called forth by my remarks, *first*, that he did not experiment on dogs in the Pathological Laboratory of the University of Pennsylvania; *second*, that he did not conclude from his experiments that the poisonous effects were produced only by the saliva of persons who did not smoke; nor *third*, by the saliva of those who lived in hot climates, implying that, by these remarks, I had inaccurately represented the results of his experiments.

At this point allow me to make a correction and to state that:

1. I did not say that Dr. Sternberg experimented upon *dogs*, but that he used *rabbits*.

2. I did not dream of implying that Dr. Sternberg laid stress upon the influence of tobacco in modifying the poisonous effects of saliva. Whether or not the use of tobacco had any such effect was a question that arose in my own mind, and I mentioned it only collaterally that the experiments made by Dr. Sternberg, and later by Dr. Claxton, to determine this point were attended by negative results.

3. Dr. Sternberg's experiments appear really to show that the saliva of persons who lived in hot climates has more poisonous effects.

The rest is quoted in accordance with what I said, and is correct. It is evident, however, that Dr. Sternberg did not read carefully my statements, and misunderstood them. I fail to see where he has found it stated that Dr. Claxton obtained *results* differing much from his own (Dr. Sternberg's). I said that Dr. Claxton at that time came to different *conclusions*. I

did not question the correctness of the *results* of the experiments of Dr. Sternberg; these are certainly reliable; but I am perfectly at liberty to draw from them *conclusions* of my own, and even if these differ from those of Dr. Sternberg, it does not necessarily follow that I made "inaccurate statements" or "deductions."

Finally, I would like to explain that at the time when I made those brief remarks at the meeting of the West Philadelphia Medical Society, Dr. Claxton's experiments were not published. There may have been a misunderstanding; but from what I had seen of these experiments of my distinguished pupil, and from what he (Dr. Claxton) told me, I was justified in saying, "that any saliva, even that of animals, promptly killed those experimented upon." To this conclusion Dr. Sternberg will also come, if he will experiment with animal saliva, and will continue the experiments with human saliva. Dr. Claxton has limited himself, however, in his paper (*Philadelphia Medical Times*, June 17) to the record and the discussion of the experiments with normal human saliva, and hence it is perfectly proper for him to say there, that the results obtained accord, for the most part, with those of Dr. Sternberg.

Feeling now challenged, I must give the reasons why I am unable to agree with the *conclusions* my friend Dr. Sternberg draws from his saliva experiments.

Dr. Sternberg was the first to fully establish the virulence of normal human saliva. This is the main thing, and has great merit. But his experiments are not extended enough to prove his conclusion that the lethal effects are due to a poison peculiar to the saliva, and, moreover, by no means warrant his deduction, that only certain saliva has poisonous effects, and that some saliva lacks such properties, viz., does not kill rabbits.

I will relate some incidents from our experimental laboratory (University of Pennsylvania) in close connection with the last-named facts, and which suggest that "*any and all saliva*" *kills certain rabbits, while some rabbits cannot be poisoned by any saliva or by septic material of any kind.*

First, I beg leave to refer in detail to one, a rather unusual, instance of immunity in rabbits. There remained in the laboratory a number of living animals, left over after the various experimenters of my pathological class ceased work at the conclusion of last winter's term. Among the number was a buck-rabbit which had been largely dosed by my friend Claxton with saliva of some kind. Since then, during the last six months, this same rabbit was injected subcutaneously, at different times, with all the articles of the following bill of fare:

1. Human saliva,(second time).
2. Cancer juice.
3. Epidemic diphtheritic material from Michigan.
4. Bouillon, containing a rich crop of cultured micrococci from the same material.
5. Diphtheritic material from a fatal case in the city.
6. Slough from rabbit, dead of diphtheria.
7. Slough from scarlatinal sore throat.
8. Slough from erysipelas.
9. Slough from gangrene.
10. Cadaveric poison.
11. Feces from typhoid fever case.
12. Sputa from case of phthisis.

And in spite of all these inoculations, our rabbit is to-day perfectly well and happy. Suppose, now, we happen to have many such rabbits among those experimented upon! This is not the only instance. In our experiments of this year, for the National Board of Health, on diphtheria and septicæmia (unpublished report of Dr. H. C. Wood and myself), and occasionally in former years, we noticed that in every lot of rabbits used there were a certain number which showed an immunity from the poisonous effects of nearly every kind of septic material, although I must say that the trials were not made so thoroughly as in the case of our heroic rabbit. Each of the above-mentioned agents which had failed to kill him, had promptly killed many of his fellow-creatures, experimented upon at the same time.

Again, many rabbits died from trifling interferences, viz., from the subcutaneous introduction of simple foreign bodies, etc. (see Wood and Formad, Reports to National Board of Health, 1880–'81).

We had ample opportunity to learn that we should draw conclusions only from large series of experiments. Single or only a few experiments, especially if attended with negative results, teach nothing, and may lead to wrong conclusions.

There is a great deal to be said about this matter, and many comments are necessary, but are out of place here. I may be, however, further permitted to state, that we have never seen any animal die of blood-poisoning, entirely regardless of the kind of matter inoculated, unless there was created in that animal, by the matter used, a self-propagating, local, septic, inflammatory focus promoting the growth of bacteria. The character or kind of the matter used for inoculation appears to be immaterial, as long as it is capable of exciting a septic inflammation.

Yours, respectfully,

H. F. FORMAD.

UNIVERSITY OF PENNSYLVANIA, August 1, 1882.

NEWS ITEMS.

THE APPOINTMENT OF DR. CHARLES H. CRANE as Surgeon-General of the Army has just been confirmed by the Senate.

DR. MORELL MACKENZIE, of London, sails from Liverpool to-day, on a brief visit to this country.

A FRENCH TRIBUTE TO SURGEON GEORGE A. OTIS.—The *Union Medicale* for July 18, 1882, has a long obituary notice of the late Surgeon G. A. Otis, which commences with the following lines:

"The great surgical name, which was extinguished in Washington, on February 22, 1881, did not owe its reputation to the *éclat* of a teacher, operative skill, or an appreciative practice; but it was in the modest duties of a ministerial department that the author of the Surgical History of the War of the Rebellion was able to erect the most important monument extant of military surgery."

PROF. MAREY, of the Collége de France, has been decorated with the Officer's Cross of the Legion of Honor.

APPOINTMENT OF DR. A. W. SMYTH AS SUPERINTENDENT OF THE NEW ORLEANS MINT.—A telegram from New Orleans states that "the nomination of Dr. A. W. Smyth to be Superintendent of the New Orleans Mint by President Arthur has given great satisfaction to all save the bummer element in politics. The appointee was for about fifteen years Chief Surgeon of the City Hospital, and he is universally conceded to stand at the head of Southern surgeons. His practice has been very large, and he has acquired considerable wealth. His local status is of the highest, and his character without a stain. He has acquired enough in his profession to enable him to live comfortably, and has withdrawn therefrom in a great measure. A natural distaste for the scalpel and a love for political excitement led him into accepting this appointment.

Dr. Smyth will probably be the next Republican candidate for Governor of Louisiana, with a strong probability of an election. Such is the public estimation in which he is held that the Democratic papers unite in declaring his appointment to be the best the President has ever made in this State."

Dr. Smyth is well known in the profession as the only operator, up to the time of Mr. Thomson's case, whose patient had recovered after ligation of the innominate artery.

Health in Michigan.—Reports to the State Board of Health, for the week ending July 29, 1882, indicate that dysentery has increased, and that bronchitis, erysipelas, intermittent fever, scarlet fever, and neuralgia have decreased in area of prevalence.

Including reports by regular observers and by others, diphtheria was reported present during the week ending July 29, and since, at sixteen places; scarlet fever at nine places; measles at nine places; and small-pox at fifteen places, as follows: at Wayne Co. Pest House, July 23; at Westwood, Kalkaska Co., and at Manselona, Antrim Co., July 28; at Flint (twenty-six cases), at Lansing (one case convalescent), and at Detroit, July 29; at Deerfield, Lapeer Co., July 30; at Grand Rapids, and at Grand River, Kalkaska Co., July 31; at Crystal, Montcalm Co., at Mount Morris, Genesee Co., August 1; and in Ionia Co. as follows: in Orange township (fourteen cases), in Sebewa township (four cases), in Danby township (one or two cases), and in the village of Portland (two cases), August 3.

Burial Permits in Illinois.—At a regular meeting of the State Board of Health of Illinois, held April 13–15, 1882, the following resolution was adopted:

Resolved, That in order to protect the legal interests of survivors, to facilitate the detection of crime, and to secure fuller and more accurate knowledge of the causes of mortality, whereby preventive medicine and general sanitation may be promoted, the Illinois State Board of Health earnestly recommends to the proper authorities of all cities and towns in this State, having populations of one thousand or over, the enactment and enforcement of a suitable ordinance requiring a burial permit from a designated official, and based upon the physician's certificate of death *now required by the statute*, as a condition precedent to interment within, or removal of a decedent without, the corporate limits of any such city or town.

State Board of Health of West Virginia and the Requirements for the Practice of Medicine.—At a meeting of the State Board of Health of West Virginia, held in the city of Parkersburg, on Wednesday, July 26, 1882, there were present Geo. B. Moffett, M.D., President of the Board; Geo. H. Carpenter, M.D.; C. T. Richardson, M.D.; Gabriel McDonald, M.D.; Lawrence Carr, M.D.; Wm. M. Late, M.D., and James E. Reeves, M.D., Secretary, the Hon. A. R. Barbee, M.D., being the only absent member.

The business of general interest to the medical profession transacted at this meeting, was the adoption, by a unanimous vote, of the following preamble and resolutions defining the words "reputable medical college," as they occur in the law creating the Board:

1. *Whereas*, It is one of the special duties of the State Board of Health of West Virginia to protect the people against incompetent medical practitioners; and,

Whereas, The said Board is charged with authority of law to reject applicants for medical certificates who are graduates of *disreputable* medical colleges, unless they, the said applicants, shall appear before the said Board, and pass a satisfactory examination in all the branches of the profession; and,

Whereas, The test or proof of proper reputation of a medical college is the occupancy of all needful grounds and buildings set apart for lecture and laboratory work; the possession of such mechanical and scientific apparatus or appliances as are necessary to illustrate and supplement medical lectures; a *de facto* corps of capable professors, whose curriculum embraces not only both lectures and examinations in the eight ordinary branches of medical education — namely, anatomy, chemistry, physiology, hygiene, surgery, obstetrics, practice of medicine, materia medica, and therapeutics —but also the additional and important departments of hospital and clinical instruction; a preliminary examination as a condition of matriculation; the requirement of actual (not merely nominal) attendance upon at least eight-tenths of the lectures of *two* full winter-courses; dissection, practised during one full winter-course; and, finally, strict adherence to the measure of requirements for graduation established and published by its officers and faculty; therefore,

Resolved, That the State Board of Health of West Virginia will not hesitate to refuse recognition of all diplomas granted by disreputable medical colleges.

Resolved, That nothing less than the definition or measure of requirements expressed in the foregoing preamble, or a very close approximation thereto, will be accepted by this Board as proof of the "good reputation" of a medical college.

2. *Whereas*, This Board has before it a communication published in the Philadelphia Medical News, July 22, 1882, over the signature of "D. N. Kinsman, M.D., Dean of Columbus Medical College," which gives the standard of requirements upon which the diploma of that college is issued; and having other evidence of indisputable character that the said Columbus Medical College has grossly violated its published requirements for graduation[1]; therefore,

Resolved, That this Board can no longer recognize Columbus Medical College as worthy and "reputable" within the meaning of the law from which this Board has received authority to pronounce upon such cases; and all persons applying for registration on diploma issued by said Columbus Medical College will be rejected, unless they, the said applicants, submit to an examination by this Board, and are found duly qualified to practice medicine, surgery, and obstetrics in West Virginia.

Resolved, That this action is based wholly upon recent proceedings on the part of the Faculty of Columbus Medical College, and there is nothing in it which is intended to, or should in any manner, reflect upon the professional standing of graduates of that school prior to the year 1882.

A New Insane Asylum in Arkansas.—The new insane asylum at Little Rock, Arkansas, will be ready for the admission of patients in January next.

Porro's Operation.—On Wednesday, July 12th, Mr. Knowsley Thornton performed Porro's operation at the Samaritan Hospital. The patient was thirty-eight years of age, had been married twelve years, and in early married life had had a miscarriage; she had been separated from her husband until within the last six months, and shortly after he returned to her she became pregnant. So far as she could tell, she was about at the fourth month, and had not quickened. She had suffered from abdominal tumor for some six or seven years, but it had not troubled her till she became pregnant. It then began to grow very fast, and on admission into the hospital it filled the abdomen, pressing against the ribs above, and pushing the pregnant uterus down into the pelvis, so that a large portion

[1] See eighth Annual Announcement, page 13.

of the fœtus was below the level of the cervix, in the hollow of the sacrum. She was only moderately easy when in bed, and even then had considerable abdominal pain and occasional difficulty in breathing. She was in a weak and anæmic condition, and able to take but very little food. Mr. Thornton came to the conclusion that pregnancy could not go on; and being doubtful whether the tumor was a dermoid or solid ovarian, or a fibroid outgrowth from the uterus, determined to open the abdomen, perform ovariotomy if it was ovarian, and Porro's operation if it proved to be a sessile fibroid. It was found to have a sessile base, and an elastic ligature was first passed round the neck of the uterus and the pedicles of both ovaries temporarily, and the uterus (with fœtus, both ovaries, and the tumor) cut away. No blood was lost, except what was in the tumor, etc. A large mass of adherent omentum was ligatured off, and a Kœberlé's wire serre-nœud was then applied on the distal side of the elastic ligature, and the latter was removed. The stump was fixed in the lower angle of the wound, and treated with solid perchloride of iron. The operation was strictly Listerian in every detail. There was little, if any, shock, and the patient is now convalescent. The temperature has only once been up to 100.2°; the pulse on the second night to 108. The wound has been dressed twice under the spray, and was found dry and sweet. The patient sleeps and eats well, and has (one week from operation) a temperature of 98.4° and pulse 84. The bowels have acted well after enema.—*Med. Times and Gazette*, July 22, 1882.

ŒSOPHAGOSTOMY.—During the last session of the Clinical Society, Mr. Reeves read a paper on the treatment of œsophageal stricture, in which he advocated the operation of making a permanent opening in the œsophagus, in preference to gastrostomy, which has proved so fatal. It may be recollected that, in the second case of gastrostomy, then related by the author of the paper, healthy tube was reached *post mortem*, without great difficulty; and the impression of this case, coupled with the fact, that œsophageal stricture is commoner in the upper part of the tube, induced Mr. Reeves to recommend a cervical exploration before proceeding to gastrostomy. Recently, an opportunity has occurred to carry this plan into effect. A man, aged 63, under the care of Dr. Stephen Mackenzie, at the London Hospital, was referred for operation to Mr. Reeves, who, after consultation with his colleagues, and with the approval of Mr. Adams and Dr. Mackenzie, successfully performed the operation. On reaching the œsophagus, which was recognized with difficulty on account of its walls being cancerous, a large elastic catheter was introduced, and tied in. A further account of the case will appear in due course. Meantime, the operation is of interest, as showing that the suggestions offered by the author of the paper, at the Clinical Society, have been proved to be quite practicable, and tend to bring this rather rare and difficult operation within the range of practical surgery, and possibly to offer advantages over gastrostomy.—*Brit. Med. Journ.*, July 15, 1882.

EMBALMING.—The principal Italian embalmers keep their special processes a secret, although the chief steps are well known. The process of embalming is stated to consist of five steps: First, cold water is injected through the whole circulatory system until it issues quite clear; this may take as long as five hours. Alcohol is then injected for the purpose of abstracting all the water from the body; this is followed up by the injection of ether to dissolve out the fatty matter; this injection is carried on for several hours—in thin subjects for two, in very fat ones for even so long as ten hours. After this a strong solution of tannin is slowly injected, and full time is allowed for its soaking into all the tissues; this takes from two to five hours. Lastly, the body is exposed for from two to five hours to a current of warm air, which is previously dried by passing it over heated chloride of calcium. The body can then be preserved for any length of time without undergoing change, and is as hard as stone.—*Lancet*, June 24, 1882.

PRECAUTIONS AGAINST FIRE IN THEATRES.—The horror of the Vienna theatre fire and the revelations of the trial recently concluded have borne fruit in a plan for establishing official control over all the theatres of the empire, so far as public security is concerned. The Minister of the Interior has sent out to all the provincial governors the framework of a bill to be submitted to the several Diets, of which the following are the main provisions: In every town where there is a theatre, a local commission is to be appointed, composed of representatives of the municipal authorities, the police, the medical profession, the fire brigade, and impartial experts. These are to exercise a general supervision. Further, a similar local commission, but comprising members of the Diet, is to be attached to the Stadtholder's office in each province. All new theatres are to be detached from other buildings, and are to contain no store or printing-rooms. Every inflammable substance used in the performance is to be impregnated with fire-resisting fluids; and the most minute precautions are to be taken for insuring proper inspection. It will also be provided that there shall be an open gangway between every six rows of seat, that a shaft for the escape of smoke shall be erected, and that the number of the audience shall be strictly limited to the capacity of the theatre.

OBITUARY RECORD.—At Cincinnati, on August 1st, of apoplexy, WILLIAM HEBERDEN MUSSEY, M.D., aged 64 years. Dr. Mussey was born at Hanover, N. H., September 30, 1818, and graduated from the Ohio Medical College in 1848. He was prominent during the Rebellion for his services in the Union cause, and was one of the most efficient medical officers in the service. At the close of the war he was appointed Professor of Surgery in Miami Medical College, which position he held at the time of his death. During his lifetime Dr. Mussey gave to the Cincinnati Public Library five thousand volumes and twenty-five hundred pamphlets as a nucleus of the "Mussey Medical and Scientific Library," designed as a memorial of his distinguished father the late Dr. Reuben D. Mussey.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT, U. S. ARMY, FROM AUGUST 1, 1882, TO AUGUST 7, 1882.

MUNN, C. E., *Captain and Assistant Surgeon.*—Granted leave of absence for one month, with permission to apply for two months extension, when relieved by Assistant Surgeon T. H. Pleasants.—*S. O. 147, Department of the Missouri, July 28, 1882.*

SHUFELDT, R. W., *Captain and Assistant Surgeon.*—The leave of absence granted him in S. O. 92, April 21, 1882, from A. G. O., is extended one month.—*S. O. 178, A. G. O., August 2, 1882.*

HOPKINS, W. E., *First Lieutenant and Assistant Surgeon.*—To proceed from Fort Adams, Rhode Island, to Camp Washington, Gaithesburg, Maryland, and report to the commanding officer for duty.—*S. O. 132, Department of the East, July 31, 1882.*

THE MEDICAL NEWS *will be pleased to receive early intelligence of local events of general medical interest, or which it is desirable to bring to the notice of the profession.*

Local papers containing reports or news items should be marked.

ORIGINAL LECTURES.

ON BRONCHITIS IN CHILDREN.

A Clinical Lecture.

BY WILLIAM T. PLANT, M.D.,

PROFESSOR OF CHILDREN'S DISEASES IN SYRACUSE UNIVERSITY, SYRACUSE, NEW YORK.

GENTLEMEN: The subject that claims your attention this morning is bronchitis. Though not essentially different from the same disease in the adult, its extreme frequency in early life entitles it to special consideration.

By bronchitis, we understand an inflammation of the lining of some and possibly all of the bronchial tubes. It is a malady characterized by great differences as to severity and danger. It may be so mild as scarcely to merit notice, or so severe as to defy treatment and lead to speedy death.

Its most frequent cause is exposure to cold with dampness. It is, therefore, like other acute affections of the respiratory organs, much more likely to occur in the fall, and winter, and early spring than in midsummer.

You will not wonder that it sometimes occurs epidemically, when you reflect that a state of the atmosphere that would favor its advent in one person, might, with equal reason, render multitudes of others liable to it. Influenza is the name given to epidemic bronchitis. In our climate, it is, I think, most common in March and April. In some seasons it is exceedingly severe, affecting indiscriminately all classes and ages.

Often, too, bronchitis is secondary to other diseases. In fact it is a pretty constant attendant on measles and whooping-cough, and pneumonia, and pulmonary phthisis. In croup, diphtheria, scarlet fever, and the continued fevers it frequently appears as a troublesome and dangerous complication. Dentition also seems to favor attacks of bronchial catarrh, and you will have frequent occasion to notice the concurrence of the two conditions.

The symptoms vary, as you would suppose, with the extent and intensity of the inflammation. In its simplest form we know it as a "cold on the chest," and it is apt to be preceded and attended by the usual phenomena of a coryza. There is sneezing and nasal discharge; the eyes are suffused; the head feels stuffed; very likely the throat becomes sore, and soon the child begins to cough. If old enough, it may complain of tightness and soreness over the chest. In young infants there is often an outcry with every cough. As the thorax becomes affected, relief is apt to come to the head and throat, as if the cold had moved downward.

The cough, at first, is harsh and dry, because the usual moisture of the bronchial tubes is diminished or suppressed. If, at this early stage you lay your ear to the chest, you will hear, besides the respiratory murmur some sonorous and sibilant râles. After two or three days the secreting function of the bronchial mucous membrane is restored and the cough becomes loose and rattling. Indeed, it is more than restored, for the secretion is changed in quality and largely increased in amount. Thin and colorless at first, it soon becomes semi-transparent and thicker, and a little later is yellowish and opaque. It now consists of mucus and pus and an abundant crop of epithelium. Children are so slow in learning to expectorate that when under four or five years of age the sputa are generally raised to the throat and swallowed.

Auscultation at this time of free discharge discovers coarse, moist râles with both respiratory movements. The sense of constriction across the chest has been relieved by the exudation, and the cough ceases to be painful. There has probably been at first a little fever, with lassitude, and some lessening of appetite. These symptoms may last for three or four or even ten days, when the cough and discharge begin to diminish, and there is a speedy return to health. This is a true bronchial catarrh, and, in strict speech, should not, perhaps, be called a bronchitis, for it is doubtful if the mucous membrane is more than hyperæmic.

Not all cases are thus benign. The bronchial tree has numerous branches of many sizes, and the above description applies to a condition in which only the larger ones are involved. If the inflammation dips down into those of smaller calibre, the disease becomes more severe and dangerous; or, if it extends still further, and invades the ultimate twigs—capillary bronchitis—the situation becomes, to the last degree, painful and desperate. Occurring secondarily to other diseases, or in weakly children, bronchitis is apt to be severe, and in young infants even the simplest bronchial catarrh is liable to dangerous and fatal extension.

In the severer forms, the symptoms are pronounced and unmistakable. The cough is frequent and painful. There is dyspnœa, more or less distressing according to the extent of the inflammation and the age of the child. The nursling suffers most, because it must so often relinquish its hold of the nipple to recover its breath. The call for air may be so urgent that all the muscles auxiliary to respiration are actively at work. The inspirations may mount to sixty, eighty, or even one hundred a minute.

The fever, though considerable, is of varying intensity, and you will often notice, as in many other febrile states, a morning remission and an afternoon or evening increase. The relation in frequency of the pulse to the respiration is apt to be changed. Normally there are three or four pulse-beats to one breath. In capillary bronchitis the ratio may be two to one, or even less. So great a change is indicative of extreme peril.

There is great restlessness, as is always the case when the want of air is urgently felt. Secretion, when established, is usually abundant, and auscultation reveals numerous moist râles, both large and subcrepitant. They may also be detected by palpation almost as readily as by the ear. They are especially numerous below and posteriorly, for to these parts of the chest the fluid tends by gravitation. The percussion note is resonant, unless obstruction of bronchial tubes has occasioned pulmonary collapse, or a considerable portion of lung substance has been invaded by the inflammation. Probably in the young child instances of serious bronchitis are rare in which the inflammation is strictly confined to the tubes. Often small circumscribed portions of pulmonary tissue are found to have been inflamed, but the condition is not easy of detection during life.

If the disease continues and extends, other symptoms declare themselves. An inflammation involving the smallest tubes of both lungs cannot long exist without causing marked disturbance of the circulation. Though

the inspirations are ever so frequent, too little air passes through the diminished calibre of the bronchioles to supply the increasing want. The pulmonary vessels refuse free circuit to unoxygenated blood, and the right heart and all the venous system become surcharged. The lips and extremities grow livid, the face takes on a bluish pallor, the temperature falls, and a cold sweat stands on the head, and perhaps covers the general surface. Soon there are marked signs of carbonic acid poisoning. The cough, hitherto so troublesome, abates; the restlessness gives place to quiet indifference; the respirations grow more frequent and shallow; the pulse becomes reduced to a flutter, and then disappears; coma usually and convulsions occasionally precede death.

Such is the course and frequent termination of capillary bronchitis. It is not always fatal. You will meet with cases—not very often, it is true—where the outlook for a time is dismal enough, that do at length recover. A lessening of the dyspnœa is one of the earliest signs of amendment. The disease seldom lasts as an acute affection longer than two weeks. In young infants it has been known to be fatal within forty-eight hours. The return to health after a severe attack is apt to be interrupted by frequent backslidings, especially in cold and changeable weather. It may even degenerate into a chronic bronchial catarrh. Children who have a trend toward phthisis, or are otherwise in delicate health, are liable to this form.

A word or two as to the post-mortem appearances in case of death. There will be redness and swelling, and probably softening of the bronchial mucous membrane. It may look and feel like scarlet-red velvet, owing to intense hyperæmia. These appearances will, of course, be coextensive with the antecedent inflammation. The smaller tubes may be found filled with the muco-purulent exudation that before death gave rise to such distressing dyspnœa and abundant moist râles. If you make pressure upon a cut section, you may observe a drop of this fluid starting from every tube. Very likely you may meet, along the free borders of the lungs, patches of collapsed tissue, for bronchitis is one of the most frequent causes of acquired atelectasis. Frequently, and especially in the lower lobes, you will come across isolated patches of lobular pneumonia, too small to have been detected during life.

Treatment.—A simple bronchial catarrh or "cold on the lungs" calls for little treatment. It is rather for what it may become than for what it now is that it is worth a careful looking after.

Probably an emetic given as soon as the child begins to cough would bring many cases to an abrupt end. We are not often consulted early enough for that. While the cough is yet tight and painful, I try to hasten the coming of the stage of secretion by giving an expectorant as follows:

℞.—Pulv. Ipecacuanhæ, . . . grs. vij
Pulv. Ext. Glycyrrhizæ, . . grs. iij
Sacchari Albi, ... ℥iss
Aquæ, ... ℥iij—M.
Signa.—A teaspoonful every second or third hour; if it nauseates, give less.

When the patient is robust, and more than three or four years of age, I often add to the above .06 grm. or one grain of tartar emetic. Another good plan for children of this age and habit is to give from three to six drops each of wine of ipecac and wine of antimony, with a teaspoonful of sugared water. If restless and feverish, I order a hot foot-bath at bed-time, and give—

℞.—Pulv. Doveri, ... gr. ½–j
Pulv. Ipecacuanhæ, . . . gr. ½
Sacchari Albi, ... grs. xv—M.

I think it well to get the derivative effect of a laxative, as castor oil; or—

℞.—Pulv. Rhei,
Hyd. cum Magnesiæ, . . . āā grs. ij.
Signa.—Ft. chart.
Repeat after a few hours if necessary.

The patient should be kept in-doors at least until the cough is loose and painless. In most instances, from two to five or six days of such care will be all that is necessary.

But if the attack is more severe, as shown by dyspnœa and high fever, there is occasion for more watchful care and more vigorous treatment. The air of the apartments should be evenly moist and warm. As an expectorant, the first formula above given will answer, or something like the following will serve you well:

℞.—Syr. Ipecacuanhæ, . . . ℥vj
Syr. Scillæ, ... ℥iij
Vini Antimonii, ... ℥ij
Syrupi Simp., ... ℥iss
Aqua Menth. Pip., . . . ad. ℥iv—M.
Signa.—A teaspoonful once in three or four hours.

If the child is delicate, or under two years of age you had best omit the antimonial wine.

Applications to the chest make an important part of the treatment. Nothing suits me so well as a poultice made of ground mustard and flaxseed in the proportion of one part of the former to from eight to fifteen parts of the latter; stir this into a paste with warm water; spread evenly and not too thickly on muslin; cover this with a thinner cloth and stitch around the edges. This may be long enough to go around the chest, and wide enough to reach from clavicle to umbilicus. Surround this with a layer of oiled silk or other impervious fabric. This poultice should be worn for hours; if too irritating for this, the mustard should be reduced to the point of tolerance. With some thin-skinned young infants you may find it best to leave out the mustard altogether. Indeed, the oil-silk jacket alone will often serve you a good purpose.

Henoch, a recent German author, surrounds the chest with a cloth wrung from cool water, a layer of cotton batting and an oil-silk covering. He advises a renewal of this dressing so often as every half hour if there is much fever; or once in an hour or two if the fever is inconsiderable.

While my preference is for the mustard and flaxseed, it must be conceded that the frequent changing of the cool water dressing would tend to prevent pulmonary collapse by compelling deep inspirations.

Some authors, recent as well as old, counsel dry-cupping of the chest, I am not averse to this practice, but am of the opinion that we have a more effective derivative and counter-irritant in the above applications, because they act on a much larger surface.

After secretion is established, it is apt very soon to become super-abundant. The loosening mixtures prescribed at first are henceforth out of place. The medicines from which we may now derive the most benefit are of those known as stimulating expectorants. One of the best of these is carbonate of ammonium. The following is a pretty efficient combination:

℞.—Ammoniæ Carb., ... grs. xxx
Syrupi Senegæ,
Tinct. Opii Camph., . . . āā ℥ss
Syrupi Tolutani Bals., . . . ℥iss
Aquæ, ... ad. ℥iv—M.
Signa.—A teaspoonful every third or fourth hour to a child of one year.

I would have you remember that these stimulating expectorants are not admissible during the first stage

of bronchitis. If given before secretion is free they can do no good but may do harm.

When there is troublesome dyspnœa from accumulating secretion, you may secure prompt, though too often but transient, relief from an emetic. For this I have always resorted to ipecac; there are other drugs as good. By all means avoid powerful depressants like antimony.

If late in the disease there are signs of carbonic acid poisoning, be chary of emetics, as they usually fail to act, and add to the prostration. In this condition Dr. Day, an English authority on children's diseases, advises chloroform with ammonia; here is his formula:

℞.—Ammoniæ Carb., . . . grs. iv
Chloroformi, ... ♏xx
Syr. Bals. Tolutani, . . . ℥ss
Aquæ, ... ad. ℥ij—M.

Sig.—A teaspoonful for a child of one year.

Though opiates are to be used warily in acute bronchitis, they are occasionally necessary. I have seen a single grain of Dover's powder, coupled with a warm foot-bath, carry a two, three, or four years old child from a state of extreme restlessness to one of comparative comfort and repose. But when secretion is abundant and the dyspnœa considerable, you will have a care not to induce a profound or a prolonged sleep by opium or other narcotic.

Do not allow your youthful zeal for medication to cause you to forget the importance of proper support. In severe cases, with labored breathing, strength is lost rapidly unless the nutritive processes are kept active. Give milk or animal broths often, and give stimulants. Infants, like aged people, bear well, and often need stimulants in acute diseases.

Furthermore, in bronchitis a frequent change of position is not only allowable, it is necessary. Do not attempt to keep the infant on its back, for thus the secretion gravitates to the posterior parts of the lungs, and stays there. But change frequently, as, indeed, the instincts of the little one prompt it to do for itself. Lying on the stomach across the nurse's lap is a posture especially favorable to the gravitation of the discharge towards the mouth.

When a child has a chronic bronchial affection the first step towards its successful treatment is to ascertain the cause. If you find it to be syphilis, or scrofula, or tuberculosis, you will shape your treatment accordingly. An occasional emetic does good by clearing the tubes and stimulating them to a healthy activity. Steam inhalations, suitably medicated, and stimulant embrocations to the chest are of service.

℞.—Lin. Saponis, ... ℥iij
Tinct. Capsic., ... ℥iiss
Aqua Ammoniæ, ... ℥iv—M.

Signa.—Apply daily to the chest, with friction. For many cases cod-liver oil is a prime remedy.

In some children, one cold follows so closely on the heels of another that the bronchial tubes are seldom free. This tendency to cold-taking may be overcome by daily exercise out of doors without any extra wrapping of neck and chest, and a cold sponge-bath nightly at bed time. Some cases of chronic weakness and catarrh of the breathing tubes are surprisingly bettered by a change of residence.

IRRIGATION OF THE COLON.

By CHARLES W. DULLES, M.D.,
SURGICAL REGISTRAR TO THE HOSPITAL OF THE UNIVERSITY OF PENNSYLVANIA.

As we are now getting into that season when diseases of the intestines carry off the greatest number of victims, I desire to call attention to a method of treating inflammations of the colon, which has never —as far as I know—been at all generally adopted or even understood in this country; although it is not uncommonly practised in Europe. It is not difficult or dangerous; on the contrary, it is simple and easy to carry out, and it cannot possibly do harm. The method was called by Dr. Alois Monti, of Vienna, whom I saw practice it often in 1876 and 1877, "irrigation of the large intestine."

It is carried out in the following manner: The patient being placed on the side, or back, or with the belly downwards, and the pelvis a little elevated, a large, moderately flexible catheter, if for an infant or a child—or a stomach tube, if for an adult—is inserted into the rectum. To this is attached, by a tube, a reservoir of water,[1] the height of which can be varied as may be required.

The water is now allowed to flow from a height of about two feet until the rectum is distended; meanwhile the end of the catheter or tube in the rectum is pressed gently but steadily upward toward the left iliac fossa. Very soon it will be found that the water has opened out the folds of the bowel and straightened the curves, so that the tube finds its way beyond the sigmoid flexure and into the descending colon. Unless the operator be very unskilful it may now be pushed gently on, the flow of water continuing without interruption, until it reaches the left hypochondrium, when the transverse colon becomes the descending.

The flow of water is now to be continued until the whole colon, all the way to the cæcum, has been gently distended; the operator assuring himself of this by the amount of fluid used, and by palpation and percussion. The tube is now withdrawn and the operation is complete.

The fluid remains in the bowel a variable length of time. Sometimes it begins to come away in a few minutes: but it sometimes remains a half an hour or more.

This method I have seen used by Monti, for various inflammatory disorders of the large intestine, as well as to cause expulsion of worms and flatus; and I have myself used it a number of times with results calculated to give me great faith in its usefulness.

The most striking case, I now recall, occurred in 1878, when I was summoned in the night to an infant a few months old, whom I found screaming and struggling with the pains of acute colitis. I took it on my knee, had cool water and a fountain syringe brought, attached the silver catheter from my pocket case, oiled it and slipped it first into the rectum and then up to the bend of the colon, and allowed about a pint and a half of water to flow in at that point. As the water filled the bowel the child's struggles and cries ceased, and it actually went to sleep before I was done, and only waked when the water began to be discharged.

Such striking results cannot be considered the rule, of course; but there can be no doubt that so complete a lavement must be of advantage in

[1] A fountain syringe or any of its substitutes serves this purpose well.

soothing the angry lining of the bowel and diluting and bringing away both the cause and the products of irritation.

To fill in the outlines of the method a little, I will add that in general the fluid used should be cool, not cold, water. It is rarely necessary to use astringents. When they are desired, the best is alum, in a one or two per cent. solution, with perhaps a few drops of laudanum added. The irrigations may be frequently repeated; and, in cases that do not get well promptly, various temperatures may be tried—from 70° or 80° to 40° Fahr.—depending on circumstances.

The amount of fluid to be used varies with the age of the patient. It should always be enough to fill the *entire* colon. An unweaned infant may require more than two pints, an adult several quarts.

No real syringe should be used if hydrostatic pressure can be obtained; though, if this is not to be had, I have found the syringe, carefully and slowly used, will serve very well.

Thus far I have referred mainly to such intestinal troubles as are most frequent in summer. The method is, I think, invaluable in all inflammatory affections of the colon, from diarrhœa to dysentery, and useful—for reasons I can not go into now—in inflammation of the small intestine also.

Before leaving the subject, I want to speak of another use which I learned by experience last winter. I was called into the country to see a child about two years old, whom I found in convulsions. The use of revulsives had been tried without effect. I could get nothing into its mouth to produce vomiting or catharsis. The means at hand were very limited. I was satisfied from the history that the convulsions were due to irritating ingesta. I concluded to see if they were in the colon. So I took my silver catheter, attached it to a syringe, passed it through the anus, distended the rectum, pushed the catheter up till I could feel it through the abdominal wall, just below the left costal cartilage, and filled the whole colon with warm water, in which a little soap had been stirred. After about three minutes, the water came away and brought a mass of undigested and indigestible stuff that was quite sufficient to cause the trouble. The convulsions stopped, and the child got quite well.

From this case, I think, a useful hint may be gathered, and I am sure I shall repeat my experiment the next time I have to treat a case of convulsions due to intestinal irritation.

I recall attention to this method because I think it too valuable to be allowed to be forgotten; and I hope that it may prove a helpful adjunct to our other therapeutic resources against intestinal disorders.

ON THE PROPHYLAXIS OF PUERPERAL FEVER.[1]

By RUDOLF TAUSZKY, M.D.,

ATTENDING PHYSICIAN AND SURGEON TO THE MOUNT SINAI HOSPITAL, OUT-DOOR DEPARTMENT (DISEASES OF WOMEN), ETC.

Within the past few months quite a number of parturient women, many of whom were attended by midwives, or by physicians with but a limited obstetric experience, have died in this city in consequence of the diseases generally comprised under the name of "childbed or puerperal fever," who, in my opinion, could have been saved had the proper prophylactic and remedial agents been used in time, in accordance with the views published by Prof. Carl v. Braun, of Vienna; Barnes, of London; Prof. Fordyce Barker, of this city, and many other well-known authorities, both here and abroad, too numerous to mention, who have made the subject under consideration their special study.

My own experience in the art and science of obstetrics, extending now over a period of more than a quarter of a century, obtained as early as 1855, in the lying-in wards of the University of Pesth, in Hungary, under the late Prof. Semmelweis, and having been quite extensive, I deem it in the interest of science to publish it, with a view of calling the attention of the profession to the fact, as will be proved by a few statistical quotations from lying-in wards abroad, that the death-rate from puerperal fever can be diminished to a minimum—hardly one per cent.—if the measures which I will enumerate further on be adopted for the prevention and the cure of puerperal fever.

Already as early as 1847, Prof. Semmelweis, then of Vienna, enunciated the now well-known fact that puerperal fever, so called, was caused by a contagious or infectious *materies morbi*, communicated to parturient or pregnant women by the hands or instruments of accoucheurs, midwives, or nurses; especially was this the case in lying-in institutions, causing, according to Kiwish, a death-rate of eighty per cent. from septic pyæmia. Up to the time mentioned, the various febrile diseases affecting women during the puerperal state were termed by Cruveilhier and others "hospital fevers." Semmelweis maintained that the cause of these fevers was not to be ascribed solely to confinements taking place in hospitals or lying-in institutions, but that the septic material was often brought into these institutions from without, from dissecting-rooms, or from patients who had been suffering from infectious diseases. Semmelweis proved his assertion by experiments upon rabbits and other animals, upon whom he produced pyæmia and septicæmia by introducing into their genitals decomposed putrid matter, obtained from the bodies of persons who had died from infectious or septic diseases; and, again, he demonstrated that one animal thus inoculated and infected, was, in its turn, a source of infection, producing the same fatal results in other animals, either during the latter part of their pregnancies, or after having given birth to their young.

Hausmann's experiments, in 1868, instituted upon rabbits, by injecting fluid taken from a cadaver where death resulted from infectious peritonitis, inevitably caused the death of the pregnant animals, even if their genital tracts were uninjured, provided, however, the experiment was instituted shortly before or soon after labor—nay, even the injection of healthy pus into the genitals of female animals, at the time mentioned, if their vaginal or the mucous membranes of the uterus were wounded or injured,

[1] Read before the Obstetric Section of the New York Academy of Medicine.

caused always pyæmia and death; but the effect was negative if pus, serum, or blood was thus injected upon the genital mucous membranes of unimpregnated animals. Not every septic fluid produced ill-effects upon the uninjured mucosa of the unimpregnated animals, but it was, on the contrary, inevitably followed by a fatal result if applied in cases of uninjured genitals shortly before or during labor, thus showing conclusively the great susceptibility to infection with consequent fatal results during the advanced pregnant or the puerperal state.

Childbed fever attacks the wealthiest as well as the poorest women. It attacks child-bearing women of all ages, and of varying constitutions, especially those suffering from primary endometritis and vaginitis during pregnancy, who are then liable to parenchymatous metritis and metrophlebitis after childbirth. The catarrhal secretions, according to Braun, often cause catarrhal ulcerations of the denuded mucosa, which then becomes the gate of infection and the starting-point of phlegmonous inflammations. Some cases of puerperal fever undoubtedly originate from the absorption of the foul stuff of decomposition from retained blood-clots, portions of undelivered placenta, the membranes, purulent matter formed in utero, or from wounds or bruises, and subsequent gangrene of the tissues of the genital tract, where the puerpera takes the poisons of her own making, especially in cases of tedious or instrumental labors, which Barnes appropriately terms autosepsis, self-empoisonement; but by far more frequently do we find puerperal septicæmia caused by the introduction of septic matter from without, called by the same authority "exosepsis," in his article on antiseptic midwifery in the January number of the *American Journal of Obstetrics* of this year.

Primiparæ, especially older persons, are oftener attacked than pluriparæ, especially during the winter months, when not only its frequency, but, at the same time, the mortality is greatly augmented. In winter, erysipelas, phlegmonous and catarrhal affections of the cellular tissues and the respiratory tract occur oftener than at other seasons of the year, so that, for the same reason, inflammations of the genitals during the puerperal state are often the products of the same influences.

The death-rate from puerperal fever is far greater than from small-pox. From the latter only 3 persons died out of every 100,000 inhabitants in 1875, since the law of compulsory vaccination had been enforced in Prussia, while in the same year 39 per 100,000 inhabitants died there from childbed fever.

A commission appointed, in 1878, by the German Government to investigate this subject ascertained the fact, in addition to what I already quoted above regarding mortality, that 8872 women die annually in Prussia of puerperal diseases without being in all cases the consequences of difficult or dangerous, but often of easy and natural, labors. During the year mentioned 60,209 women, who were under fifty years of age, died from all diseases; of these, 12.09 per cent. lost their lives from puerperal fever in the country mentioned.

One of the most frequent causes of the diseases during the puerperal state, as reported by the same authority, fully confirmed Semmelweis's views above referred to, viz., that many otherwise healthy women who were attacked by puerperal fever were beyond doubt proved to have been infected by one and the same attendant, even if the labors were natural ones. This view of the possibility and transmissibility of the puerperal-fever poison is shared by Schroeder, M. Bochr, Fassbender, H. Martin, Lochlein, and many other authorities.

I am acquainted with a physician, who some years ago lost quite a number of patients, who died of puerperal fever—septic or pyæmic—while under his care. Being followed by such ill luck, he finally left this city and went abroad for a time, to avoid being the direct and, of course, the involuntary cause of any more deaths among his patients.

Nearly 500 women in the prime of life, lose their lives annually, in this city, from eclampsia parturientium et puerperarum, puerperal peritonitis, metrophlebitis, pyæmia, or lymphangitis. In Vienna, "Allgemeines Krankenhaus," from 1834 to 1848, of 39,156 women delivered, 3,486 died; from 1849 to 1863, 61,170 births and only 998 deaths; from 1863 to 1878, 61,949 deliveries and only 825 deaths from puerperal fever. In 46 years, of 162,275 women (of these, nearly 100,000 were delivered under the supervision of Carl Braun), 5,309 died of childbed fever. By examining these interesting figures as published by Braun, I was convinced of the fact, not generally known, that before Semmelweis's teachings had been heeded the mortality in the Vienna lying-in institution ranged, annually, between 5 and 10 per cent. and over; while since the precautionary measures which I will presently enumerate were adopted, the death-rate never exceeded 1.3 to 2.5 per cent.

These means, as practised in Vienna, I have myself adopted and applied during my practice of obstetrics, and I am able to state that I have never had the misfortune of losing a single case in my own practice from puerperal fever.

This good luck I do not claim as being due entirely to good management on my part. It will be impossible, as far as our present knowledge is concerned, to prevent the occasional occurrence of puerperal fever under the best hygenic, dietetic, medical, and surgical treatment, but I maintain without fear of contradiction that we can reduce its percentage, and are able to prevent the spread of the infection from one parturient to others who are healthy at the time of labor, and even after tedious instrumental deliveries we may save many lives which would otherwise be inevitably lost.

The prophylactic measures are briefly the following: The hands of every attendant should be carefully cleansed and disinfected with a 3 per cent. watery solution of carbolic acid or other disinfectant, and afterwards oiled with carbolized oil of the same strength, before examining the genitals of the parturient or pregnant woman; for the removal of the bad odors from the hands, a one-half per cent. solution of permanganate of potash is used; for the black stains caused by it, a 10 per cent. watery solution of dilute hydrochloric acid is applied until the

hands become bleached. The bowels of the parturient should in all cases be moved by an enema of white Castile soapsuds, a whole basinful, with one or two tablespoonfuls of melted lard; the water should be drawn if necessary by a catheter (soft rubber, Nélaton's) which has been thoroughly cleansed and disinfected. The hand should never be introduced into the uterine cavity in natural labor. The vagina and vulva to be disinfected with a lukewarm watery solution of thymol or salicylic acid, 1 part to 1000 aq., with the addition of 3½ parts of glycerine and 7½ of alcohol, in case the thymol be preferred. This cleansing injection is to be used in every case of labor before parturition, but after delivery injections are only found to be useful after difficult operations, very tedious, protracted deliveries, especially after the artificial separation of the placenta, internal version. The uterine cavity is washed out in these cases preferably by a fountain syringe to which a flexible, well-cleansed, and disinfected rubber tube is attached.

The thymol or salicylic acid, lukewarm, of the strength mentioned, is safer than carbolized water. The solution is allowed to flow into the cavity with the least pressure, and in sufficient quantity, from one to two or more quarts at a time, until the water returns free from shreds, blood, mucus, etc., and has only the odor of the thymol; whenever the lochia become in the least offensive, the injections are to be repeated. I have used them in cases of the artificial separation and removal of the placenta, etc., with the happiest results, from six to eight times during twenty-four hours. Slight lacerations of the perineum, or wounds made by episiotomy, are closely united by serre-fines, or, if extensive, by metallic sutures; bruised wounds of the vagina should be pencilled with pure tincture of iodine, muriated tincture of iron, thymolized oil, or, according to Fehling, with salicylic powder (one to five of starch) applied two or three times a day. Under this treatment, they usually heal in from three to five days.

Free ventilation, and the utmost cleanliness in and about the lying-in room, *cannot* be substituted by any amount of disinfection. The thorough disinfection of the utensils, the bedding, and all instruments in use ought rigidly be insisted upon; all emotions are to be scrupulously guarded against: the secretory and excretory organs of the patients should be kept in as healthy a condition as possible. Chilliness of the patient should be carefully obviated, and the thermometer used twice daily in the well-dried axilla of the patient. The child is applied to the mother's breasts about two hours after delivery, as soon as she has had some rest, and no tea or other food allowed the new-born except a teaspoonful or so of sugar water in very hot weather. The care of the mother's breast deserves special attention, since fissures, eczema of the nipple, often cause pain, nervous excitement, restlessness, and often fever. Cold applications—tannin and glycerine, slight touching with nitrate of silver or Peruvian bark 4, to 8 of almond oil, 6 of mucilage of gum arabic, and 35 of rosewater, applied every hour, will heal sore nipples in a few days.

To obviate hemorrhage post-partum, is to oppose septicæmia, says Barnes, justly. I therefore always give 4 grammes (3j) of fluid extract of ergot (Squibb's or Wyeth's), even in natural labor after its completion, and repeat the dose, given in sugar water, until the uterus has firmly contracted, and it becomes evident that no portion of the placenta, the membranes, or of blood has remained in the vagina or the uterus. The least hemorrhage from the genitals is treated by tincture of iodine, persulphate of iron, hot-water injections, the silver wire, or carbolized silk ligature. Contrary to the teachings of the Vienna School, I apply the abdominal binder and a pad or napkin over the uterus. This practice, also recommended by Barnes, tends to aid in contracting the uterus, and, moreover, counteracts the suction or aspiration force and the entrance of air into the genitals, one of the factors of putrefaction. I differ, however, from Barnes, as being unnecessary, to make intra-uterine carbolized injections, 2 per cent. solution once or twice daily from the second day, or even after natural delivery. I use injections only when the lochia are offensive. I deem it superfluous, and even dangerous, to use vaginal or intra-uterine injections after natural labor, unless indicated as stated above. If fever symptoms appear, as shown by the thermometer placed in the axilla, I also syringe the vagina several times a day, but not otherwise. The intra-uterine injections are used in puerperal fever with great benefit, still, in Germany, there are more opponents to, than advocates of, intra-uterine injections; they prefer drainage tubes of soft rubber in suitable cases. Before draining the uterine cavity, or making injections into the same, the straightening of the ante- or retroflexed uterus has to be resorted to, otherwise these means cannot be usefully applied. Frankenhauser (1879) considers the prophylactic intra-uterine injections post-partum the cause of many unfavorable terminations, especially as the cause of a considerable rise in the temperature. He justly says we run the risk of thereby introducing air, and are never sure of washing away all the putrefying material from the uterine mucosa. He objects to intra-uterine injections, as well as the introduction of the hand into the uterus, unless absolutely unavoidable. If the latter becomes necessary, he does it under the carbolic spray. He even examines all his patients before, during, and after labor under the carbolic spray. Salicylic water injections are also sometimes followed by evil consequences. He says: "I have had no untoward symptoms from intra-uterine injections with salicylic water in cases where I had to introduce the hand into the uterus for adherent placenta, turning, atony, and post-partum hemorrhage; but I object to the indiscriminate use of disinfectant solutions after normal labor as an unnecessary and meddlesome procedure."

Many cases of child-bed fever being caused by the infection from one case to others, the immediate isolation seems as imperative as if it were a case of cholera or small-pox.

This precaution is now rigidly carried out in all lying-in institutions with the happiest results, as detailed by Tarnier at the last International Congress held in London. Its quotation may be of use to those who are not familiar with this excellent

method. He says, "Even in 1856, when I was Interne at the Maternité Hospital, the mortality was five per cent., this was now reduced to two per cent. in hospital and three-quarters of one per cent. in the pavilion I had constructed a few years ago. Each patient there has a separate room, entered from without, so that a nurse can only pass from one to another by going outside into the open air. The furniture is of japanned iron, the floors, walls, ceilings are of impermeable concrete. The mattresses and pillows are stuffed with cut chaff, which is burnt after use in every single case. Instead of McIntosh sheets, one of brown paper, made impermeable by pitch, is used; this is burnt after use." For the washing of the genitals, he uses weak solutions of bichloride of mercury, as being the best and most powerful germicide.

Dr. Fancourt Barnes, in the British Lying-in Hospital, delivered all his patients under the carbolic spray. All washings, syringings, and examinations are done with carbolic solution; spray (1 to 80 aq.) is continually playing in the ward. To secure uterine contraction, each patient has a mixture of quinia, ergot, and opium, three times a day, for the first week. Since instituting this treatment, he rarely finds it necessary to use intra-uterine injections, and only exceptionally finds any rise in the temperature during the lying-in. I deem the proper prophylactic measures of disinfecting the utensils, the air, the hands, the instruments in and about the lying-in room, of the utmost importance, and I have quoted, at length, authorities in support of the correctness of this practice, the more so, since a short time ago I read, in the *New York Herald*, a lecture by Prof. Chandler, of the New York Health Board, who asserted that money spent for carbolic acid was practically wasted. He says it does not kill germs of disease! Sacicylic acid, thymol, permanganate of potash, *bichloride of mercury*, and in fact all the chlorides and sulphates, etc., will kill vermin, and destroy animal and vegetable life if used in sufficiently large quantities, and even by its moderate, non-poisonous application, we can surely prevent putrefaction by the agents mentioned, as proved by the microscope. If, for instance, the bacteria and micrococcus of diphtheria be examined with a magnifying power of, say, five hundred diameters, they are seen jumping and dancing helter-skelter on the stage within the visual field, and if the same bit of membrane showing these organisms be placed in a solution of carbolic acid, they soon die and show no sign of life at all. It is true, we have only the means at our command to prevent putrefactive changes; if these have once taken place, we have no agents which will restore the putrefied substance to its former healthy condition.

Antiseptic surgery and also antiseptic midwifery have already stood the test of time as to their high value, and we need not fear that as preventive, though not as curative, agents against infectious diseases, these will ever be found wanting.

Rest after delivery in the recumbent posture with the head and shoulders raised, for the purpose of aiding uterine drainage, for at least eight or nine days, should in every case be insisted upon. Many women in this city delivered by uneducated, ignorant midwives, especially among our foreign population, are poisoned and often killed by having the infection brought to them by their attendants, whom I have often found to neglect the necessary cleanliness and ventilation of the lying-in room. Soiled clothing, urinals half or quite full of decomposing urine, fecal matter, and lochial discharges, left there for hours, no doubt become the foci of puerperal-fever poison. All midwives should, therefore, have a license from the city or State authorities before being allowed to attend confinement cases, and should be examined as to their fitness for assuming the great responsibility during the agonies of the parturient, often victimized, woman. The licensed midwife should be furnished with printed rules by the health authorities, similar to those recommended in 1878 by the puerperal fever commission, viz., that in confinements the putrefaction of the secretions of the mother be prevented; that the labor be terminated before there is any offensive discharge from the vagina; that the causes of putrefaction, the cocco-bacteria, be destroyed by thorough disinfection; that all the attendants be instructed to use disinfectant vaginal injections in all protracted and tedious labors, and to disinfect their hands in all cases before making a vaginal examination; to report to the sanitary authorities every case of puerperal fever occurring in their practice; that puerperal fever be classed among the infectious and contagious diseases; that the authorities be notified even of the occurrence of every case of high fever during or after childbirth.

To prevent the spread of puerperal fever, midwives, unless licensed, should not be allowed to attend confinement cases, making such attendance punishable by a fine and imprisonment. Every attendant should carry a two per cent. solution of carbolic acid to every labor case. Instead of diapers or sheets, carbolized cotton, tow or oakum should be used under the genitals to receive the lochial discharges, and be burned before becoming offensive. Among tenement-house occupants, I have often noticed the throwing of the after-birth into the privies and water-closets, where they decompose and are the cause of many infectious diseases. The health laws in this country say nothing regarding the disposal of the after-birth, which should be burned or buried in every case. Baths are thought to be injurious during confinement and even during pregnancy, not only by the laity, but also by many physicians. If the parturient can be conveniently lifted into a bath-tub and immersed for a few minutes in it and removed to her bed without the least exertion on her part, I know of no preventive measure against puerperal fever which surpasses its utility. If these means were generally carried out, a very small percentage of women would die from childbed fever—especially after natural labor.

CASE OF INTESTINAL OCCLUSION.

BY L. D. WILSON, M.D.,
OF WHEELING, WEST VA.

OBSTRUCTION of the bowels, while by no means rare, possesses features of peculiar and striking interest. The generally sudden onset; the usually previous good health of the person attacked; the extreme distress and suffering accompanying it; and the almost certain and speedy death to which the sufferer is doomed, all combine to excite the liveliest emotions of sympathy; while the paucity and, for the most part, the inadequacy of our remedial resources are the occasion of many melancholy reflections. The difficulty of determining in a given case either the seat or the cause of the difficulty is in most instances perplexing in the extreme; and the treatment, instead of being based on a rational consideration of the actual conditions present, is forced to take counsel of doubt and conjecture. To carefully and succinctly note the symptoms and pathology of every case that may differ in either respect, no matter how minutely, from those which are already understood, is the only way in which our knowledge as respects diagnosis can be widened; and this must furnish the excuse for presenting the following case:

CASE.—On the afternoon of May 6, 1882, I was called to see C. F., a widow, aged sixty-five, of spare habit, and somewhat broken by age. She was complaining of a severe pain in the left hip, which had come on suddenly during physical exertion, and which seemed to extend from thence across the lower portion of the abdomen just over the region of the bladder, until it almost reached the opposite side. There had previously existed considerable lameness in the left leg, the origin of which I was not able to learn, except that the leg was affected about the time of the menopause, some fifteen years before. She ascribed this lameness to "change of life, which," as she expressed it, "had settled in the hip." There was stated to be some shortening of the limb, and also that at various times in the past she had suffered from attacks of pain similar to the present, except that in the previous attacks the pain seemed to be limited to the hip and limb. These preceding attacks of pain always seemed to be caused by some unusual exertion or fatigue, and this last attack was ascribed to the same cause, as she had been, for several days before, much more actively engaged than usual in household duties. She had also been troubled for many years with frequently recurring colicky pains in the lower part of the abdomen, and the stomach and bowels would almost daily be more or less distended with gas, giving rise to frequent eructations. Her appetite had long been poor, and the bowels alternately constipated and relaxed, and latterly she had been oppressed by a gradually increasing feeling of weariness and fatigue. After a day of unusual exertion, as before stated, and while still at her work, she was seized with this sudden pain, which was soon followed by vomiting. An examination developed the following condition. There was marked tenderness on pressure over the region of the bladder; some fulness of the abdomen, but neither hardness nor tenseness on manipulation, and no indications of any tumor or enlargement of the viscera. The pulse was full and regular, and but little accelerated; the tongue very slightly furred, and moist; and the skin slightly yellow. There was no headache; the temperature seemed to be normal—no record of it was taken, however—there was no disturbance of breathing, and the mind was perfectly clear. The bowels had not acted on this day, but there had been a slight motion on the day before. Owing to her evident suffering, and desire for speedy relief, no special investigation of the condition of the limb was undertaken for the present, especially as she was used to such attacks, and a hypodermic injection of morphia was given over the left hip, and a morphia mixture ordered at intervals until pain should be relieved, after which a mild cathartic was directed to be given. At the visit the next morning it was found that the pain in the hip had been almost completely relieved; the tenderness over the lower part of the abdomen was somewhat less, the fulness and softness remaining unchanged; but there had been frequent vomiting of a bilious character during the night, and the bowels had not been moved. This, of course, excited no surprise, as all the medicine given for that purpose had been thrown up almost as soon as taken. Urine had been passed in moderate quantity; the skin was still natural; and the tongue not changed. On inquiry at this visit, it was learned that she had had a hernia many years before, but that it had never given her any trouble. Examination revealed on the left side the hernial opening, which freely admitted the index finger almost to the second joint, and which seemed to be occupied by a sac, which gave the impression to the finger of being considerably thickened at the depending fundus. This was freely movable; could be readily pushed up as far as the finger could reach; and there was no hardening, pain, tenderness, nor, indeed, any indication of strangulation. As the stomach was quite irritable, all internal medication was suspended, except such as was directed to the relief of this symptom, and hot applications were ordered over the tender region of the abdomen.

On the third morning, the patient was found to be in much the same condition as on the day before, except that the tenderness over the abdomen was very much diminished, but there was rather more fulness; the vomiting had continued, the stomach rejecting everything taken into it. Other measures for the relief of this symptom were directed for the day, and an enema was ordered in addition. The patient was visited again about 5 o'clock P.M., and there was found but little change from her condition in the morning. The tenderness over the abdomen had almost disappeared; but while the abdomen was still soft and pliable, it seemed rather fuller. The pulse was still full and regular, but somewhat accelerated; the skin cool and moist; the tongue moist and velvety. The vomiting had been much less frequent, but there was about the vomited matter, which was of a dark-brownish color, and liquid, a faint fecal odor. She complained, too, that the remedies used to quiet the stomach caused some

oppression about the chest, and, on this account, they had not been regularly continued. The enema had been given, but nothing was brought away. As it was now plain that there was obstruction or strangulation of the bowel at some point, no further efforts were directed to the stomach, but as the patient's general strength seemed but little affected, it was deemed best to give the treatment by enemata a further trial. This was accordingly directed, and instructions given for fully carrying it out. About midnight, I was hastily called, the messenger stating that she was much worse. I saw her shortly afterwards, with Dr. A. F. Stifel, of this city, in consultation. We found her apparently much exhausted; pulse 102, weak and somewhat irregular; skin cool; countenance shrunken; vomiting frequent, and of a very marked stercoraceous character; abdomen somewhat fuller, but still soft, and but slightly tender on pressure. She had been so averse to being disturbed that the directions in regard to the treatment given at my former visit had not been carried out. After a careful examination, it was agreed that the only alternatives remaining to us were either that of persevering with the enemata, or the desperate one of opening the abdominal cavity and attempting to relieve the difficulty by such further procedure as might be indicated. This latter plan was at once rejected by the patient and friends, but, after some persuasion, we were permitted to make a further trial of the former. Accordingly, a rectal examination having revealed nothing, an enema was given, which at once passed away without any result. After waiting half an hour, another was tried, with no better success. As the patient was averse to any further efforts to relieve her, it was, at the suggestion of Dr. Stifel, agreed to put her fully under the influence of opium. Accordingly, one-third grain of morphia was given hypodermically, and she was left for the remainder of the night. At the visit next morning, Dr. Stifel accompanying me, the patient was found more comfortable; had slept during the intervals between the acts of vomiting, which had been much less frequent; the pulse had recovered strength and regularity, and was somewhat less frequent; the abdomen, with the exception of somewhat further increased fulness, was unchanged; skin cool; and the secretion of urine, which had been very scanty the day before, was again moderate in amount. Morphia, one-third grain, was again administered, and the patient left. At the evening visit, she was found to have passed a more comfortable day than at any time since her illness began. The pulse was full, regular, and about 94; skin cool; mind clear, with less mental depression; abdomen yet further enlarged, but still without anything like tenseness or hardness in any part, and but very slightly tender on pressure, the tenderness, as at first, being limited to the lower part. The vomiting, however, still continued. Brandy and water, which had been given frequently in small quantities for the last day or two, although vomited soon after being taken, was directed to be continued; morphia was again given, and, as the patient seemed disposed to allow it, an enema of olive oil was directed. On the next morning, I found the patient dying. Cold, pulseless, shrunken, and wandering in mind. The olive-oil enema had been given without result; but the vomiting had almost entirely ceased during the night. Throughout the entire course of the attack, there had never been any straining or inclination to have a movement of the bowels. Death took place about 11 o'clock A.M., on the fifth day of her illness.

Autopsy.—After some hesitation, a post-mortem examination of the parts chiefly implicated was allowed. This was made about nine hours after death. The body exhibited marked cadaveric rigidity, and the abdomen was much distended. Upon opening the abdominal cavity, and drawing the omentum aside, the coils of the small intestine which first showed themselves were found to be distended with gaseous and dark liquid contents, but there were no adhesions between these distended coils, no deposit of lymph on their serous covering, nor were there any special evidences of congestion. On drawing them aside, the colon was found only moderately distended with air only, neither liquid nor solid matters being noticed. Upon the left side, a prolongation of the omentum was found extending downwards, and upon examination it was found to extend into the hernial sac before mentioned, and to have formed very strong adhesions within it, but there was no stretching or strangulation. The adhesions were so lax that the imprisoned omentum could be easily drawn out as much as two inches before putting them on the stretch, and so large was the ring, that the finger could easily be introduced alongside of the omental prolongation as far as the bottom of the sac. All these manipulations were very carefully and cautiously made so as to disturb the parts as little as possible. Returning to the cæcal region, the appendix vermiformis was found to be unusually long; the ileum at its entrance into the colon was empty and completely collapsed, and on tracing it carefully backwards quite a number of coils, some of them very slightly adhering to each other, were found, and all of them in this empty, corrugated condition. After having traced the ileum in this manner for more than a third of its length, a sharp bend, almost an angle was found, and just before the collapsed portion merged into the angle, it abruptly enlarged and continued as the distended portion from thence to the duodenum and stomach. In contact with this angle or knuckle, another knuckle of the distended portion of the bowel was lying, very much as in the closed fist one finger lies against its fellow, and between them a recent and very slight adhesion had formed, the adherent surfaces not being larger than a gold dollar. Within the angle of the occluded knuckle of intestine was an old cicatrix about one inch in length. This cicatrix had evidently been parallel with the long axis of the bowel, and its contraction had been the means of producing the sharp angle which existed, and also no doubt caused a narrow stricture of the bowel at this point. Surrounding the angular knuckle, and about one inch from its apex, was an indistinct marking, as if caused by the knuckle having been held for a long time against the hernial

ring while slightly protruding through it. At the distal end of the cicatrix, reckoning from the pylorus, and at the point where the adhesion existed, there was moderate inflammatory thickening, evidently recent, of the intestinal coats, and this no doubt converted the stricture from a permeable into an impermeable one. So complete was it that neither liquid nor air could be made to pass through it. No other organs were examined.

Remarks.—In reviewing the history of this case in connection with the autopsy, the first question that arises naturally is—To what cause was the very slight and circumscribed inflammation at the seat of stricture due? The first thought would be that it most probably had been caused by the lodgement in the constriction of some solid substance taken with the ingesta; and this, indeed, may have been the case, but no satisfactory evidence that such had been the case was discovered. Not to multiply surmises, the conclusion arrived at was as follows: That an adhesion between this knuckle of bowel and either the portion of omentum included in the hernial sac, or a part of the hernial ring, had existed for an indefinite period, perhaps from the time the hernial protrusion occurred; that the occasional attacks of pain which had always been referred to the hip and limb, were in reality located at the point where this adhesion existed, and were caused by some dragging or partial laceration of the fibres forming it; that, finally, some unusual strain caused the adherent parts to separate, the rupture of the adhesions exciting just enough inflammation to cause the slight thickening necessary to close up the already narrow passage. This hypothesis seems to fully explain the difference between the final and the previous attacks of pain in the hip. All the previous attacks had been limited to the hip and limb only, while the last one seemed to extend across the abdomen over the region of the bladder, and it was just back of this viscus that the occluded knuckle was found, where it had fallen against another portion of intestine and a slight adhesion between them had formed.

Stricture of the bowels caused by the process of cicatrization is quite rare. In a table of the causes of obstruction in 1547 cases given in Ziemssen, Ency., *Constrictions*, and under this head are grouped chronic kinks, different kinds of stricture, constriction by chronic peritonitis, adhesion, etc., occurred in 106, or about 7 per cent. Of this number, the short time at my disposal prevents any attempt at ascertaining the ratio of cases caused by cicatricial contractions to the other causes grouped under this head, but it must be extremely small. The causes of cicatricial stenosis are but few and of rare occurrence. Healing of dysenteric and tubercular ulcers are the most common, corrosive poisons rarely, and in very rare instances typhoid ulcers (this is much disputed), arrested fecal masses, foreign bodies, separated intussuscepta, syphilitic ulcers, etc. Rare as the cases of stricture of the intestines are, but a very small proportion of them are located in the small intestine. In 100 fatal cases of stricture given by Brinton, only 8 were situated in the small intestine. Bristowe states (Reynolds' Syst. Med.) that "stricture as a cause of death belongs, almost without exception, to the large intestine, and not only so, but at least three-fourths of the total number of strictures are situated below the middle of the transverse colon." This, of course, would be expected when we remember that the few causes of cicatricial stricture of the small intestine, viz.: Tubercular and typhoid ulcers, corrosive poisons, foreign bodies, separated intussuscepta, etc., must very rarely be present. It should also be stated that cicatricial stenoses have been found in both large and small intestine, of which no satisfactory explanation could be furnished. In all the list of causes of intestinal cicatrices, no one is found which seems at all likely to have been concerned in its production in the case under consideration, but that its causation was connected in some way with the hernia there seems little reason to doubt. On account of the very rare occurrence of cicatricial stricture of the small intestine, it might be well, perhaps, to make a comparison of the symptoms observed in this case with those of intestinal obstruction in general, and to note the points of similarity and difference.

1st. *Pain.*—This is one of the most usual symptoms in cases of obstruction. It may, and usually does, partake of the characters both of peritonitis and colic, although either may exist without the other. Painful peristalsis is the cause of much suffering and distress in most cases. The pain in the present case seemed to be altogether that of peritonitis, the actual pain lasting but one day, after that the condition was simply one of tenderness, which steadily and rapidly diminished. As in all cases of chronic stricture of the bowels, this patient was subject to recurring attacks of colicky pain previous to the final symptoms of obstruction, slight indiscretions in diet or undue physical exertion serving to excite them.

2d. *Vomiting* is stated to be "rarely if ever absent in these cases," and it is also thought to come on earlier and to be more persistent and severe, the nearer the lesion is to the stomach; the character of the vomited matters, too, is thought to be much modified by the seat of the occlusion. In this instance the different character of the ejecta followed in the usual order: 1, Contents of the stomach; 2, bilious in character; 3, then rapidly assuming the stercoraceous character. Vomiting usually continues to the last, although, as in the present instance, it may become much less frequent during the last hours.

3. *Constipation* is, however, the most characteristic symptom, and, in complete obstruction must, of necessity, always be present. In permeable strictures, on the other hand, especially when situated in the small intestine, it may not be prominent, and may even alternate with a relaxed condition.

4th. The *abdomen* is almost always more or less distended and tympanitic, but where the occlusion is high up there may be, on the contrary, flattening or retraction. Where the obstruction arises from fecal accumulation, tumors, intussusception, gallstones, etc., the cause may sometimes be recognized by palpation of this region, provided the conditions are favorable. Distention in this case was not

a marked feature, although it slowly and steadily increased, and there was tympanites from the first.

5th. *Urine.*—The condition of the secreting function of the kidneys was at one time thought to furnish an indication of the location of the difficulty. A marked diminution or suppression of the urine was thought to indicate that the lesion was high up, and on the other hand, if it was situated in the lower part of the ileum or in the colon, the urine would probably be normal in quantity. Later observations, however, do not confirm this. In the present case, the obstruction being near the middle of the small intestine, it would be supposed that the urinary secretion would be but little interfered with. In point of fact the urine was somewhat diminished at first, and on the third day it was scanty, but afterwards the quantity increased to a fair amount.

6. *The mode of attack* is a valuable aid to the diagnosis. Strangulation and intussusception are nearly always sudden in their onset; obstruction by gall-stones is almost always preceded by symptoms indicative of their presence; stricture and compression are more likely to be preceded by a train of symptoms such as presented themselves in the case before us, but it is also stated (Ziemssen) that a constriction not unfrequently remains latent for a time, and then suddenly goes on to occlusion.

7. *Prognosis* in these cases is very grave. Life may continue for several weeks, where the obstruction is in the lower colon or rectum. Death occurs more and more rapidly as the lesion approaches the stomach. In any case where enteritis or peritonitis supervenes, death follows rapidly. The average duration of an acute occlusion is given as six days, and varies from eight hours to thirteen days (Ziemssen).

8. *Treatment.*—It is not now proposed to go into a discussion of the subject of treatment. The rules governing the management of these cases are pretty clearly laid down, and in only one respect is there likely to be much variation from the present practice. The recent and brilliant achievements in the field of abdominal surgery force upon us the conviction, that operative procedures will play a much more prominent part in the future management of these cases than heretofore. Of all the causes instrumental in the production of obstruction, one only, viz., fecal accumulation, is in any proper sense amenable to treatment in any other manner. In all the others, palliative and expectant measures are the disappointing alternatives, and a careful consideration of the results attained by these fully warrants the conclusion that in an exploratory operation lies the greatest, and in the vast majority of cases the only, hope of relief.

CASE OF OUTWARD DISLOCATION OF THE RADIUS AND ULNA.

By JOHN A. SIEBER, M.D.,
of Ferdinand, Indiana.

In a paper on outward dislocation of the radius and ulna, which Dr. D. Johnston read before the Kentucky State Medical Society (see *Louisville Medical Herald*, 1879), he claimed the case he then narrated to be the second reported by an American surgeon. The majority of cases on record are from the French, who quote eleven complete outward dislocations of both bones. Prof. Gross says (*System of Surgery*, vol. ii. p. 144), lateral dislocations of both bones at elbow-joint, besides being extremely rare, can scarcely occur in any other than an incomplete form, and as a consequence of severe injury extensively implicating the soft parts; this undoubtedly is incorrect, as the case which I had under treatment and that reported by Dr. Johnson clearly prove.

The case which I now record is that of a little girl about nine years of age, who was returning home from school on the evening of November 21, 1881, when the accident occurred; it was while crossing a brook over which was placed a round log, and nearing the end she fell a distance of about two feet; the position of her arm while falling I was unable to learn; about two hours after the accident occurred I saw the patient at her home; found her in a sitting posture, crying, with her forearm nearly at right angles and resting the limb on her lap.

I requested the mother of the little patient to remove the sleeve of the dress from the injured arm; when I was astonished at the dimensions of the joint, thinking it impossible to have swelled to such a degree in so short a time; proceeding at once upon an examination, I could find no contusions nor lacerations, nor crepitation, and found that the enlargement was not due to swelling, but to a complete outward dislocation of both bones.

The internal condyle was very prominent, the skin stretched very tensely over it. Externally the olecranon process of the ulna could be distinctly felt with its neighbor, the radius, rotating in the lesser sigmoid cavity; the external condyle was beneath the radius, and required firm pressure to be distinguished; both the biceps and triceps were uncontracted and flaccid, and any attempt at flexion or extension brought forth piercing cries, while pronation and supination were not so seriously interfered with. I requested the father of the little patient to get his conveyance in readiness that we might take her to town, as it was necessary to administer an anæsthetic and also to procure assistance. Accordingly we proceeded to the office of E. J. Kempf, M.D.; here she was placed under the influence of chloroform (Squibb's); the doctor also examined the case very carefully and verified my diagnosis.

As to reduction, it was easily accomplished; grasping the elbow-joint with my left hand, and the wrist with my right, I made extension and gradual flexion; with the hand encircling the joint, the olecranon was pressed inward, and both bones slipped readily into place with the usual soft snapping between the articular surfaces.

The arm was put up in the ordinary dressing with card-board splints, and placed in a sling; the parents instructed to report in a few days, or earlier, should the child complain of pain. The case progressed favorably, and in due course of time the child regained full use of its arm.

HOSPITAL NOTES.

TREATMENT OF FRACTURES OF THE UPPER EXTREMITY IN THE HOSPITALS OF PHILADELPHIA.

(Reported by H. R. WHARTON, M.D.,
SURGEON TO THE CHILDREN'S HOSPITAL, PHILADELPHIA.)

THE treatment of fractures of the humerus, in the hospitals of Philadelphia, presents some variety in dressing depending principally upon the situation of the fracture.

Fractures of the shaft of the humerus are generally treated by first applying a roller bandage to the injured arm, from the tips of the fingers to the shoulder; a binder's board or leather splint is then softened in warm water and moulded to the rotundity of the shoulder; this should be long enough to extend down the arm to a short distance above the condyles, and should include about one-half of the circumference of the arm. An internal angular splint long enough to extend from the axilla to the tips of the fingers is padded with oakum or cotton and applied to the inner surface of the arm, and held in position by a bandage applied from the fingers to the shoulder, which includes the shoulder cap, and may be finished with some spica-of-the-shoulder turns.

To complete the dressing, a sling only is required, which should be so applied as to bring the point of support near the wrist, so that the weight of the tissues between the point of support of the sling and the fracture may exert some extending force.

This dressing is usually changed after twenty-four hours, and subsequent dressings are made less frequently; the dressing is usually dispensed with at the expiration of from four to six weeks, if union has progressed satisfactorily.

For fractures of the humerus high up, that is, at the anatomical neck, upper epiphysis, intracapsular, or of the tuberosities, this dressing is somewhat modified.

The arm is extended and the initial roller, and the binder's board or leather cap of the shoulder, are applied as previously described; a folded towel or a few thicknesses of patented lint are then placed against the chest and the arm is brought firmly to the side of the body, which acts as a splint. The arm is now secured in this position by turns of a bandage which encircle the chest, and extend from the elbow to the shoulder, and the forearm is carried in a sling as previously described.

In fractures about the upper third of the humerus, where the action of the deltoid muscle causes an outward tilting of the lower end of the upper fragment, some difficulty is experienced in maintaining the fragments in line; to correct this, Prof. Agnew recommends that, when the internal angular splint has been applied, the arm should be elevated to bring it to a right angle to the body, with a view of relaxing this muscle, the cap of the shoulder and bandage which secures the dressings to the arm should then be applied while the arm is in this position, and generally serve to prevent a recurrence of the deformity when the arm is dropped to the side and secured in the sling.

Dr. Levis, of the Pennsylvania Hospital, mentions a case in which this displacement was so marked and persistent that the arm was treated in this position for some time, until there was enough union between the fragments to prevent the recurrence of the deformity, when the arm was placed in the usual position.

Fractures of the condyles of the humerus are treated by replacing the fragments by manipulation as far as possible, then applying a roller bandage from the tips of the fingers to the shoulder, with a few figure-of-eight turns about the elbow to allow of flexion for the application of the splint; a well-padded anterior angular splint, extending from a short distance below the shoulder to the tips of the fingers, is next applied and held in position by a roller bandage, and the arm is carried in a sling.

Prof. Agnew, in addition to this dressing, recommends that a leather or binder's board cap extending a few inches above and below the joint be applied to the posterior surface of the elbow; he also in certain cases uses a Stromeyer's splint, so that the angle at which the arm is placed may be changed from day to day without disturbing the dressings, and in all cases insists on early passive motion to prevent stiffness of the joint.

Some surgeons in the treatment of this fracture use the internal angular splint, applied in the same manner as in the dressing for fractures of the shaft of the humerus.

The splint is permanently removed at the expiration of four weeks and the patient is encouraged to use the arm to overcome the rigidity, which, to a greater or lesser extent, generally follows these injuries.

Dr. Allis[1] treats these fractures with the arm in the extended position without a splint, and gives fixation to the fragments by means of strips of binder's board or leather, held in position by a bandage or strips of adhesive plaster, and claims that the resulting deformity and impairment of motion is less under this method of treatment.

Fracture of both radius and ulna, or, as it is generally described, fracture of both bones of the forearm, is treated by making extension from the hand to overcome the deformity; two well-padded splints, a little wider than the forearm, and long enough to extend from the tips of the fingers to the elbow, are then applied to the dorsal and palmar surface of the forearm, and held in place by a roller bandage.

In applying the anterior splint, care should be taken that it does not press against the brachial artery at the bend of the elbow when the arm is flexed, which has been followed by the most disastrous consequences.

Having applied the splints, the arm should be carried in a broad sling suspended from the neck; the forearm should be kept in a position between pronation and supination, that is, with the thumb looking upwards. This position offers the widest separation of the bones; and, in case of redundant callus, or inward displacement of one of the fragments, gives the patient the best chance of retaining perfect motions of pronation and supination. When there is a tendency to lateral displacement of one of the fragments, this can be corrected by the use of a compress.

This dressing is usually retained from four to five weeks. Prof. Ashhurst, in dressing this fracture, applies two splints, an anterior splint extending from the fingers to the bend of the elbow, and a posterior short splint extending from the elbow to the wrist, and prefers that the forearm be carried in the supine position, as advised by Lonsdale; this position he thinks most important when the fracture of the radius is in its upper portion, preventing union with axial deformity where the upper fragment may be supinated by the action of the biceps muscle.

Fracture of the olecranon process of the ulna is treated, first, by the application of the initial bandage from the fingers to the shoulder; and if there be displacement of the fragment by the triceps muscle, it is replaced and held in position by strips of adhesive plaster or by figure-of-eight turns of the bandage about the elbow. The arm is now placed upon a well-padded, anterior angular splint, with the angle so obtuse as to

[1] Proceedings of Phila. County Med. Soc., 1878-'79, p. 79.

hold the arm in a position of moderate extension, this position being found more comfortable for the patient than that of absolute extension. A straight splint with extra padding corresponding to the position of the bend of the elbow fulfils all the indications. Either of the above splints are applied and held in position by a bandage, and are permanently removed at the expiration of five weeks.

Fracture of the radius at its upper portion, or fracture of the ulna alone, are treated with the same dressings that are applied in fractures of both bones of the forearm. Fractures at the lower portion of the radius—those described as Barton's, Colles', or Smith's fractures of the radius—are generally treated upon the Bond splint, which consists of a piece of light wood, carved into somewhat the shape of the forearm, and on the lower portion of this a block is fastened in an oblique direction, over which the fingers rest, and this, from its oblique position, causes abduction of the hand when grasped by the fingers, and corrects the adduction so often seen in these fractures.

The deformity on the palmar and dorsal aspect of the wrist is corrected by extension and by the use of two compresses, one applied over the upper end of the lower fragment, and the other applied over the lower end of the upper fragment. The splint and compresses are then held in position by a roller bandage, and the forearm is carried in a sling, with the hand in a position between pronation and supination.

The splint, in addition to correcting the adduction of the hand, allows moderate motion of the fingers without disturbing the fragments; it is usually retained for four weeks, then laid aside, and motions at the wrist encouraged.

The pistol-shaped splints of Nélaton are also occasionally used.

Dr. Levis,[1] for the treatment of this fracture, has devised a splint of tinned copper, moulded to fit the forearm and hand, which is made either for the right or left hand, and when applied allows the hand to remain in a moderately flexed position, a compress is also used on the dorsal surface of the wrist; he insists upon a perfect reduction of the fragments before the application of the splint, as a most important factor in the production of a good result.

Fracture of the metacarpal bones are treated by the application of a short palmar splint, well padded to fill up the concavity of the palm of the hand, and if there be a projection of the fragments upwards it is remedied by the use of a compress; the compress and splint are then held in position by a roller bandage.

Fractures of the phalanges are treated by the use of a long, straight splint, extending from the tip of the injured finger to the wrist, and by two or three short splints applied to either side of the finger; the long splint may be applied either upon the palmar or dorsal aspect of the finger.

The splints may be held in position by a narrow bandage or by strips of adhesive plaster.

A binder's board splint moulded to the injured finger and held in position by a bandage, strips of adhesive plaster, or by a plaster-of-Paris bandage, is also sometimes employed in the treatment of these injuries.

MEDICAL PROGRESS.

Atropine as a Cause of Glaucoma.—Atropine has of late years been so widely used in ophthalmic practice, both in the treatment of various painful affections, and also merely for the purpose of paralyzing the pupil to facilitate the estimation of errors of refraction, or an examination with the ophthalmoscope, that the warning afforded by Mr. Streatfield's letter, in the *British Medical Journal*, and to be found also in a case read to the Ophthalmological Society, by Mr. Snell, and reported in the same journal for July 15, has not been sounded too soon. It thus appears, on the evidence of competent judges, that a strong solution of atropine, such as is the officinal solution of the *British Pharmacopœia*, is capable of producing glaucoma in some cases. A way out of the difficulty is afforded by Mr. Streatfield, who points out that a solution very much weaker than that provided by the *Pharmacopœia* would suffice to produce sufficient mydriasis for all ordinary purposes. Dr. Ringer has, we believe, made some experiments on this subject, and has found that a dilatation of the pupil, lasting some hours, can be produced by a solution containing what a chemist would consider a mere trace of atropine. A solution formed by diluting the pharmacopœial "liquor" with two or three hundred times its bulk of water, would be sufficiently strong.—*British Medical Journal*, July 29, 1882.

Subcutaneous Injection of Iodoform in Syphilis.—Dr. Thomann has treated a number of cases of syphilis by subcutaneous injections of iodoform; after ten or twelve injections he has always observed a great improvement of the symptoms. The preparation is composed of six parts of iodoform in twenty of glycerine, and he injects progressively thirty to seventy-five centigrammes. He has never had an abscess to occur; the iodine is to be found in the urine in about two hours; no trace of the odor of iodoform occurs in the breath, in the sweat, or urine. He also made use of a solution of iodoform in olive oil, but found it much more irritating.—*Bull. Gén. de Ther.*, July 15, 1882.

The Treatment of Hæmorrhoids by Injections of Carbolic Acid.—Dr. Charles B. Kelsey, Surgeon to St. Paul's Infirmary for Diseases of the Rectum, New York, recently opened a discussion on the treatment of hæmorrhoids, at a meeting of the New York Clinical Society, by reading a paper on the treatment by injections of carbolic acid. The paper, which appears in the August number of the *New York Medical Journal and Obstetrical Review*, opens with condensed histories of a number of cases, after which he remarks that, beginning this plan of treatment without very much confidence in it, and with the fear of causing great pain, and, perhaps, dangerous sloughing, constantly before him, the method is constantly growing in favor with him, and the more he practises it the more confidence he gains in it. With solutions of proper strength the danger of causing sloughing of the tumors is very slight. There are no objections to this method which do not apply equally to others. He has once seen considerable ulceration result from it in the hands of another; but he has seen an equal amount follow the application of the ligature; and he does not consider this as a danger greatly to be feared when injections of proper strength are introduced in the proper way. It is applicable to all cases; is especially adapted to bad cases; and may be used where a cutting operation is inadmissible. It acts by setting up an amount of irritation within the tumor which results in an increase of connective tissue, a closure of the vascular loops, and a consequent hardening and decrease in the size of the hæmorrhoid. Except when sloughing occurs, the tumors are not, therefore, removed, but are rendered inert, so that they no longer either bleed or come down outside of the body. In cases in which the sphincter has become weakened by distention, the injections will also have a decided effect in contracting the anal orifice, as injections of ergot or strychnia do in cases of prolapsus. He has used this method of

treatment now many times, and has never, except in one case, had reason to regret using it or to be dissatisfied with its results, so far as he has been able to follow them. Although slow to advocate any one treatment of this affection to the exclusion of all others, he now generally adopts this from the outset in each case, reserving Allingham's operation for any in which the injections may fail. As yet he has met with no such case. Its advantages over all other methods, provided its results prove equally satisfactory, are manifest. The patient is not terrified at the outset by the prospect of a surgical operation, is not confined to his bed, and is not subjected to any suffering. The cure goes on painlessly, and almost without his consciousness. The method requires some practice and some skill in manipulation, in getting a good view of the point to be injected, and in making the injection properly; but this is soon acquired; and he is more and more convinced that the fear of producing ulceration is an exaggerated one, and that when ulceration is produced it is a result either of a solution of too great strength, or of one improperly administered.

Ovariotomy in Switzerland.—In a recent number of the *Revue Médicale de la Suisse Romande*, Prof. Socin, of Bâle, makes some observations with regard to the statistics of his cases of ovariotomy, as recorded in a paper on the subject in a recent No. of the *Brit. Med. Journ.*, and in the above-mentioned Swiss journal, April 15, where Prof. Kocher reproduced the substance of the latter article. In both contributions, Prof. Socin's operations were placed under "cases of ovariotomy by surgeons who have operated under carbolic spray in every case," but in the English article, 12 operations, with 4 deaths, were placed against the name of Prof. Socin, whilst Prof. Kocher gives 11 cases, with 4 deaths, in his tables. Prof. Socin now states that there are two errors in the articles on ovariotomy in Switzerland, which he desires to rectify. "The first is through an omission on my own part, for I failed to record two successful cases; this raises my total to 13, out of which 4 were fatal. In the second place, it is not correct to include all my operations amongst those conducted with antiseptic precautions. My first ovariotomy was performed on February 21, 1867, my second on July 20, 1869, when antiseptics were not in vogue. The next two cases come under the same category. Consequently, my first four cases, which include two deaths, one from collapse on the day of the operation, the other from septic peritonitis on the seventh day, cannot be taken into account in the consideration of antiseptic surgery." One death from shock half an hour after operation, and one from suppurative peritonitis which had existed before the operation, occurred among Prof. Socin's antiseptic cases. In the same series was a successful case of removal of a cystic ovary, in a patient who returned to hospital, two years later, with a large uterine fibro-myoma. He also successfully performed "supravaginal hysterotomy and the extirpation of the second ovary, which was healthy." —*British Medical Journal*, July 29, 1882.

Cure of Hydrophobia.—At the meeting of the Académie de Médecine, held on July 11th, M. Decroix read a paper entitled *Nine Cases of Cure of Hydrophobia*, of which the following are the conclusions:

1. It has been demonstrated that hydrophobia can be cured spontaneously.

2. It has never been proved that the cures in cases which recovered were due to the influence of drugs, and did not occur spontaneously.

3. All the methods recommended by the Committee of 1874 comprised the injection of nitrate of pilocarpine, and have rather hastened than retarded death.

4. Blunting the teeth of dogs is the best preventive of the propagation of the disease.

5. Persons and dogs suffering from hydrophobia should be left in perfect repose.—*Gaz. Méd. de Paris*, July 15, 1882.

Introduction of Aliments and Medicines Through the Nose.—Fernet and Martel (*Schmidt's Jahrb.*, 1882, 1.) have made a number of experiments to demonstrate the possibility of introducing ailments and medicines through the nostrils.

For this purpose the patient is placed on his back, in the recumbent position, while the head and the upper part of the throat are permitted to fall somewhat backward. The gum hose of a common nursing bottle is then pushed into the posterior part of one nostril, and the fluid—either containing nutritive substances or medicine—slowly poured in. In consequence of the peculiar position of the body, the floor of the nasal cavity and the velum form an oblique plane, so that the fluid mentioned flows directly into the pharynx and induces swallowing. Generally, and especially if the fluid is poured in slowly, the expected result ensues with certainity, and in a manner by no means disagreeable to the patient; only when the fluid is poured in too rapidly, a few drops may find their way into the larynx, causing the well-known irritating cough.

Fernet and Martel have employed this method successfully in persons in a comatose condition, in children suffering from tubercular meningitis, and even in newborn infants too weak to take the breast or the bottle. This method may also be successful in introducing such medicines into the stomach which, in consequence of their bitter or nauseous taste, are rejected by the patient.

Créquy recommends, for this purpose, the introduction of a flexible gum tube (catheter). If this is pushed behind the velum, the possible reflow of the fluid, by the other nostril would effectually be prevented.

Martel reports two cases: one, where, in consequence of a fall on the head, severe concussion of the brain, with trismus and utter inability to swallow, set in, and the other, a case of pneumonia in a drunkard, the patient being totally unconscious. Here the medicines—calomel and jalap in the first, musk and digitalis, in the second, case—were successfully carried into the system by the method described, and though in consequence of their severity the cases ended fatally, the procedure itself achieved its object.—*Medical and Surgical Reporter*, August 5, 1882.

Tubercular Osteo-arthritis.—At the meeting of the Société de Chirurgie, held June 28th, M. Lannelongue drew the following practical conclusions from a study of this subject:

Tubercular osteo-arthritis may occur in two different forms depending upon its phase of development. In the latent stage, when the synovial membrane is scarcely affected, any intervention is uncalled for, immobilization and extension with good hygiene being sufficient. When synovitis occurs, ignipuncture or interstitial injection will give the best results. Should an abscess occur, it should be opened, and the diseased bone sought for and removed.—*Bull. Gén. de Ther.*, July 15, 1882.

Use of Iodoform in the Buccal Cavity.—The effects of iodoform in tubercular joint affections, as well as the certain and reactionless course which non-sutured wounds of the surface or of cavities run under the application of this drug, suggested the advisability of testing its value in wounds of the natural openings of the human body; and the more so on account of the difficulty which has hitherto been experienced in carry-

ing out antiseptic treatment in those regions. Numerous operations in the buccal cavity, lately performed in Prof. Billroth's clinic, have afforded us a certain amount of experience in this direction. From April to October, 1881, eighteen lingual carcinomata were extirpated. In some of the cases a third or a half of the organ, but in the majority the whole tongue, was amputated. Simultaneously more or less of the floor of the mouth had to be removed, the excavation sometimes extending to the hyoid bone and digastric tendon, and including the submaxillary and adjacent cancerous lymphatic glands. Besides, in several instances the inferior maxilla was partially resected, or portions of the soft palate and pharynx were excised. Ligatures were, as a rule, applied beforehand to the lingual and external maxillary arteries. In all these eighteen cases a cure was the result. There was no reaction in any of the wounds, and in most of the cases there was no rise of temperature observable after the operation. There was an absence of those complications which were formerly observed after extirpation of the tongue. There can scarcely be a doubt that these favorable results stand in direct relation with the employment of iodoform, for the *technique* of the operation has undergone no alteration. The points to be kept in mind in this method of wound-treatment, as reported by Wolfler, *Centralb. f. Chir.*, are the following: When, after extirpation of the tongue and floor of the mouth, the wound made in ligaturing the arteries before mentioned communicates with that in the buccal cavity, the latter is drained by means of a tube of the thickness of a finger. If no such intercommunication exists, it is not purposely set up. In all cases the edges of the ligature-incision are brought together with sutures. After the operation, and in size corresponding to the depth and width of the wound, a strip (four-ply) of iodoform gauze, six to eight inches long and one and a half to two inches wide, is introduced into the mouth, and pressed with moderate firmness against the sides of the cavity, which it quite fills up. This small quantity of gauze suffices to keep the wound completely and lastingly aseptic. The first dressing usually remains adherent to the surfaces of the wound for from five to eight days. It does not separate of itself during these first days, and even then need not be changed if the patient is taking fluid nourishment. It must be especially noticed, however, that ordinary gauze does not adhere so certainly as that prepared in the following manner: 60 grammes of colophony are dissolved in 1200 grammes of alcohol, and 50 grammes of glycerine are added to the mixture. In this six metres of purified gauze are soaked, then wrung out, and dusted with 50 grammes of pulverized iodoform. If we compare these recent results with our former experiences after extirpation of the tongue, we must feel convinced that in iodoform we have found an agent for treating wounds of the buccal cavity, the mode of application of which is as simple as its antiseptic qualities are trustworthy.—*Edinburgh Medical Journal*, July, 1882.

Amyloid Kidney Without Albuminuria.—J. Strauss (*L'Union Médicale*) concludes a paper on amyloid kidney without albuminuria as follows:

1. In certain cases of amyloid degeneration of the kidneys, albuminuria may be constantly absent until death.

2. The absence of albuminuria is due on the one hand to the absence of a deep lesion (interstitial or epithelial) of the kidney, and on the other hand to a special localization of the amyloid degeneration. This, in such cases, bears chiefly upon the *vasa recta* of the medullary substance and implicates in a minor degree the glomerular vessels.

3. From a clinical point of view, if in a phthisic, or an inveterate syphilitic, or a subject of chronic osseous suppuration, etc., we find enlargement of the spleen and of the liver, but *without albuminuria*, we are not justified on this account in rejecting the idea of amyloid degeneration of the viscera, nor even in absolutely denying amyloid degeneration of the kidneys.

4. Those authors who date the beginning of amyloid degeneration in the economy from the moment at which they observe the presence of albumen in the urine, commit a double error, (*a*) because amyloid degeneration is far from beginning always by invading the kidneys. On the contrary, the spleen and the liver are habitually the first to be attacked, (*b*) because the kidney itself may be suffering from amyloid degeneration without albuminuria being present. It is then necessary to mistrust calculations by which it has been sought to fix the possible duration of life in subjects afflicted with amyloid cachexy, by making this date from the first appearance of albuminuria.—*Canadian Journal of Medical Science*, August, 1882.

Fissure of the Neck of the Bladder.—M. Reginald Harrison thinks that fissures commencing in the prostatic urethra, and involving the vesical orifice, are frequently causes of irritable bladder. The symptoms of fissure of the vesical orifice are analogous to those observed elsewhere. There is pain on micturition, and a sensation of contraction and dilatation at the close of the act, accompanied with a sharp stinging pain behind the scrotum which is very significant. Occasionally a few drops of blood escape as micturition terminates. The pain varies in degree in the same patient, being intense when the urine is highly acid and less so when it is neutral or alkaline. Examination of the prostate by the rectum invariably produces on pressure a sharp sensation as if a knife were piercing the gland. Similarly, the passing of a sound in the bladder is distressing. Occasionally these cases are referred to some gouty or rheumatic disorder; by the French the term *contracture du col vésical* often includes them. When this affection is considered to be traceable to either gout or rheumatism, the patient is almost invariably placed on an alkaline treatment with decided advantage, for the reason already mentioned. The improvement is, however, only temporary, and is directly traceable to the altered reaction of the urine. Vesical fissure is, however, seldom cured, though it may be palliated by such means; in addition rest and the application of a weak solution of nitrate of silver directly to the prostatic urethra are sometimes effectual.

On more than one occasion Mr. Harrison has succeeded in effecting permanent benefit by temporarily paralyzing the sphincter action of the neck of the bladder. The relief that immediately follows cystotomy in vesical fissure, otherwise irremediable, justifies the risk of a proceeding which is considerably less than that attending many other operations more frequently and less hesitatingly performed.—*Liverpool Med. Chir. Journ.*, July, 1882.

Double Uterus and Vagina.—Dr. Heywood Smith exhibited on July 27, in the theatre of the Hospital for Women, a case of rare occurrence with complete double uterus and vagina. The right vagina was rather the larger, the orifice of the left being rather hidden in the folds that the edge of the septum formed. Both vaginæ were perfect; the cervices were distinct, with small ora. Both were shown simultaneously by two specula. The sound passed upwards and rather outwards on the right side, two and a half inches, and on the left similarly to two and a quarter inches. *Per rectum*, it was found that the double uterus was united and flattened as far as the body, and the two fundi were separate and diverged, so that the whole organ

presented somewhat the shape of a Y. Menstruation was regular, somewhat scanty, with pain in both inguinal regions. Dr. Heywood Smith had seen a similar case in a young girl some years previously. Dr. Rogers, who was present, said he had seen five cases. It would be interesting if observers would report all cases of complete double uterus and vagina. This patient has been married eight years, but has never been pregnant.—*British Medical Journal*, July 29, 1882.

TREATMENT OF GENU VALGUM.—M. ROBIN (*Lyon Méd.*) has devised a new osteoclast for the radical cure of genu valgum. It consists of an iron case extending half way around the thigh on its anterior aspect, from a point a short distance above the condyles of the femur upward to the superior third of the thigh; two steel collars bind this to a piece of heavy plank, one at its lower, the other at its upper, limit: each collar is fastened to the plank by a nut and screw. This portion of the apparatus holds the femur secure. To the upper or superior portion of the lower collar an upright is securely fastened, having a slot at its upper end, at right angles to the collar and parallel to the long axis of the limb. Into this slot is fitted the end of a long lever, which extends down over the leg. A strong leather collar, large enough to surround the femur at the condyles and pass over the lever above, completes the apparatus. It will be evident that the lever will act, when pulled upward, as one of the second order, where the weight is between the fulcrum and the power. The object aimed at in the use of this osteoclast is to cause a transverse fracture, either complete or incomplete, just above the epiphyseal line of the femur in the direction from behind forward, or rather from within outward and upward. The following is the method of using it: The patient being etherized, the thigh is placed on the wooden frame, the iron splint or case is placed over the thigh and securely fastened to it by the steel collars; the leather band is placed around the lower end of the thigh, so as to grasp the condyles, and then over the lever. Just before applying the power the limb is rotated outward, and the force is applied by forcing the lever upward. The vessels and nerves, being protected by the condyles, escape any pressure. It is found that the femur is fractured just above the condyles, and that correction of the deformity can be readily made.—*New York Medical Journal*, August, 1882.

THE RADICAL CURE OF VARICOCELE.—M. REGINALD HARRISON describes his method of operation as follows: It consists in exposing the cord by a vertical incision about an inch in length and separting the veins which are most prominently varicose. These are each tied in two places with a catgut ligature. Usually three or four main veins require to be so dealt with. In addition, it will be observed that there are a number of small veins in plexuses or bundles, especially in close proximity with the epididymis, which cannot be obliterated in this way; these he destroys with a few light touches of the thermo-cautery, taking care, while this is being done, to protect the vas deferens by holding it from behind, between the thumb and index finger of the left hand. The operation is conducted antiseptically. No sutures are introduced, and the wound is left to heal by granulation. He has now been performing this operation for some years, and he is not aware of an instance in which there has been a return of the varicose condition of the veins; the cicatrix which results is of a contractile nature, such as usually follows wounds inflicted by burning, and gives a feeling of firmness to parts which previously were complained of as being unnaturally lax. It is a matter of great importance, in view of preventing a return of the disease, to destroy the small varicose veins, which can only be seen and not felt. If this is not done, obliteration only means driving the disease into new channels, already preparing to dilate.

He has operated on the spermatic veins in this way a great many times. In one instance only was any delay or danger imported into the case. This was an attack of erysipelas, which was directly traceable to the patient sitting on a draughty watercloset very shortly after the operation was performed. Though here there was delay and some danger, the result was satisfactory. As to the necessity for performing an operation with a view of effecting a radical cure, the sensations of patients, in addition to changes taking place in the testicle, are sufficient to indicate this. Hence, in deciding what is to be done, it is of importance to have under notice the various procedures having for their object the same result.—*Lancet*, March 25, 1882.

HYPODERMIC INJECTIONS OF PILOCARPINE IN SCARLATINOUS URÆMIA.—PROF. SEMMOLA has made a very important observation by which he clearly establishes the influence of pilocarpine in scarlatinous uræmia. The details of this case, which emphasize the relations too often forgotten between the skin and kidneys, will be read with interest.—*Bull. Gén. de Ther.*, July 15, 1882.

A CASE OF TRIPLETS.—Triplets occur in France but once in 8256 labors. The case reported by HERGOTT (*Ann. de Gynécol.*, June, 1882) is the only one that has occurred in the last ten years in the maternity at Nancy. It is as follows: S., aged twenty-four, nullipara, entered hospital in labor five hours. Membranes had ruptured, cervix was obliterated, os dilated one inch, auscultation reveals two fœtal hearts, one above umbilicus and to the right, the other below; on the left nothing is heard. Palpation is difficult, but one head is determined above on the right, a second is engaged. In two hours a female is born, followed shortly by a male. A third fœtus is then discovered, presenting by the breech. Is soon born, and is a male. One female and two males is usual, but, usually, the presentation for all is vertex. The placenta was double, united by a membranous band. Each fœtus had separate cords, but those of the males united and were inserted into the same placenta. Each fœtus was inclosed in separate membranes. On the third day the last child born died; the following day the second male; fifteen days after, the female. The mother recovered.—*Amer. Journ. of Obstetrics*, August, 1882.

HEART TUBERCLE.—HIRSCHSPRUNG (*Jahrb. für Kinderh.*, xviii., 2 and 3) reports an interesting case of a girl eight years old, who was a healthy looking child, but on admission to the hospital had serious symptoms pointing to the cardiac region, and represented by a tumultuous action of the heart, diffuse pulsation, increased cardiac dulness, slight cough, heightened temperature, and increased respiration. Dyspnœa and cyanosis set in, and the child died seven days after entering the hospital. A tubercle as large as a walnut was found in the internal wall of the left ventricle; a few miliary tubercles in the anterior part of the left upper lobe, and nowhere else in the lung; the bronchial glands, especially on the left side, were found in a state of cheesy degeneration, as were also the mesenteric glands; there were tubercles in the spleen and pericardium. The liver and spleen were enlarged, and the intestinal glands swollen but not ulcerated,—*Boston Medical and Surgical Journal*, August 3, 1882.

RESECTION OF THE PYLORUS.—MR. SOUTHAM says that, if called upon to perform this operation again, he should be disposed to introduce one or more drainage-

tubes into the abdominal cavity through the external wound, or through a counter-opening made in the loin, and attempt to draw off from time to time, by means of a syringe, any inflammatory effusion which might collect there, according to the plan sometimes adopted in cases of ovariotomy. As regards the operation itself, which has not hitherto been adopted in this country, it has now been performed on fifteen occasions by Billroth, Wölfler, and others with considerable success, five recoveries having taken place, and one patient was recently described as being alive and in good health—the digestive functions being in no way impaired—eight months after its performance.

It is, he thinks, therefore well worthy of further trial; but in order that it may be successful, it should only be performed in the early stage of the disease, when the pylorus alone is involved, and where the general condition of the patient is such, that he will be able to bear the severe shock which is necessarily attendant upon so serious an operation.—*Brit. Med. Journ.*, July 29, 1882.

Employment of Oxygenated Water as an Antiseptic in Surgery.—MM. Péan and Baldy have made use of oxygenated water as an antiseptic application to wounds, and think that their results will compare favorably with cases in which alcohol, either simple or camphorated, or carbolic acid, has been used. Oxygenated water has the further advantage of possessing no odor and no toxic properties.—*Gaz. Hebdomadaire*, July 14, 1882.

The Treatment of Fresh Wounds.—Dr. John Duncan draws the following deductions from his observations:

1. That when we succeed in preventing sepsis at the operation we can by this method rely on singularly simple and favorable progress, with total absence of fever, with freedom from pain, and with great rapidity of healing. It is proper to be exceedingly careful in the arrestment of hemorrhage; but even did a little reactionary oozing occur, it is only necessary to renew the dressing once, or, as he did in some of these cases, to put on an additional layer of wool.

2. That should sepsis lead to inflammatory action, it is necessary temporarily to abandon the dressing.

3. That even in septic cases it is often advantageous to continue it throughout if there be no inflammation, or recur to it when inflammation has subsided, because it is a good excipient for discharge, because it tends to diminish the amount of pus, and because it aids in keeping the part at rest.

4. That in fresh wounds so situated that they can be firmly and equably compressed the introduction of materials to secure drainage is usually unnecessary, and that if the drainage-tubes be introduced they should be removed in twenty-four hours.

5. That sepsis is less apt to occur by this method, as it avoids the risks which attend changes of dressing and movements of drainage-tubes, which, in my experience, are more fruitful sources of failure than even the original operation.—*Edinburgh Medical Journal*, July, 1882.

Dysmenorrhœa relieved by Removal of a Hyperæsthetic Hymen.—At a recent meeting of the New York Obstetrical Society Dr. Robert Watts reported the case of a patient, nineteen years of age, who said she commenced to menstruate at the age of twelve. The periods were regular, but were accompanied by a great deal of pain—a feeling of fulness and bearing down in the pelvis, and pain in the back. There was also headache, described by her as sick headache. There was disturbance of the stomach These symptoms lasted several days; the flow continued from seven to nine days. It was slow, and sometimes was in the form of clots. This condition had existed ever since she commenced to menstruate. About two years ago she consulted a physician in Chicago, who made an examination, and told her that she was malformed, and was "not a natural woman." This distressed her very much, and she continued to suffer in the same way until Dr. Watts saw her. On attempting to make a vaginal examination, he found the parts exquisitely sensitive, and was unable to introduce the finger. This he supposed was due to the existence of vaginismus, but more careful inspection revealed a very close hymen, which was somewhat elastic, and could be pushed up before the finger a certain distance, although it caused exquisite pain. In its centre was an opening large enough to admit an ordinary uterine probe. Owing to the condition of the parts, no examination could be made until after the hymen had been cut. Nothing abnormal could be discovered about the uterus. Ten days later she menstruated without any pain, without any headache, or any of the uncomfortable symptoms of which she had previously complained, and she had since remained perfectly well. She had been taking singing lessons, but her voice had become so weak that her teacher had rather advised her to discontinue them; since the operation, however, he had spoken to her of the great improvement which had taken place in her voice. Whether this change in the voice was due to the general improvement of the health, or to the removal of this source of irritation, Dr. Watts was unable to say. He had never seen a similar case.—*New York Medical Journal*, August, 1882.

Ligature of the External Carotid.—At the recent meeting of the Société de Chirurgie, on June 27, in reference to the point of election in ligation of the external carotid, M. Faraboeuf said that the principal objection urged to the situation between the origins of the superior thyroid and lingual arteries was the difficulty in finding the vessel. M. Faraboeuf, however, showed that the artery lies directly under the greater horn of the thyroid bone, and by cutting down on this point the point of election was readily found.—*Gaz. Méd. de Paris*, July 15, 1882.

Intra-uterine Vaccination.—Dr. Behm has made a number of experiments as to whether vaccination of the mother in the last few weeks of pregnancy renders the child after birth insusceptible to the vaccine virus, and his results show that while, like variola, vaccinia may be transferred from the mother to the unborn child, this result occurs very seldom.—*Berliner klin. Woch.*, July 17, 1882.

Antiseptic Treatment of Pulmonary Consumption.—Dr. J. Burney Geo describes a simple and convenient form of respirator for the treatment of consumption by antiseptic inhalation, and mentions a number of drugs with which he has had experience.

Of all these, he prefers creasote; but he also frequently uses carbolic acid and eucalyptol, with which he sometimes mixes a little camphor. Turpentine is a useful addition as an astringent, where there is profuse secretion or a tendency to hemorrhage. Camphor has been said to be a very powerful antiseptic, but it has the objection of diffusing itself very rapidly, and is unpleasantly pungent and penetrating. He has also found it a very convenient plan to mix these substances, such as creasote, carbolic acid, eucalyptol, or turpentine, with equal parts of spirits of chloroform. It helps to diffuse and vaporize these substances, and it is itself somewhat of an antiseptic; and it has also a soothing

effect on the often irritable bronchial mucous membrane. He has often seen a patient tormented with cough at night, so much so as to be unable to get any sound sleep, obtain perfect relief from this distressing symptom by using at bedtime one of these inhalations in an instrument of this kind. The quantity required for this purpose is often quite inconsiderable; it is rarely necessary to use more than twenty minims of a mixture of equal parts of creasote and spirits of chloroform dropped on the sponge at a time, and renewed occasionally as it becomes exhausted; and it is often desirable to begin with very small quantities, until the patient gets used to the vapor. Five drops of the mixture may be dropped on the sponge at a time, and gradually increased to fifteen or twenty. One of the advantages of the little inhaler he describes is that, being perforated all over, the access of air is unimpeded, while the vapor diffuses itself freely into the immediately surrounding atmosphere. With more solid inhalers, patients will often say they feel "stifled," and refuse to use them.

The substances named are, he believes, the best for continuous, or almost continuous, inhalation; for occasional inhalation, a weak iodized vapor will often be found very useful, and even a very dilute chlorine vapor is well borne by some patients.

Iodine vapor may be diffused through a room or small chamber by throwing fragments of iodine on a heated plate, as he now does; or it may be inhaled from the surface of hot water, by pouring a few drops of tincture of iodine on the top of hot water contained in a suitable vessel, and holding the mouth and nose over the vapor, with some light covering over the mouth and nose and vessel. The vapor of tar may be inhaled in the same manner. A sleeping apartment may be impregnated with tar vapor by putting some tar on a heated metal plate, or stirring a vessel containing tar with a piece of heated metal of any kind. Other antiseptic substances which are not volatile or are vaporized with difficulty may be inhaled in solution in the form of spray. A Siegle's spray-producer is the instrument usually employed for this purpose.—*British Medical Journal*, July 11, 1882.

SALICYLATE OF SODA.—PINSKER (*Archiv f. Kinder.*, ii., No. 12) concludes from a large number of observations on the use of this drug in children, that its ill effects, such as loss of appetite, nausea, vomiting, ringing in the ears, giddiness, deafness, at times appearances of collapse, albuminuria, erythema, and urticaria, are oftenest seen when the drug is impure. While finding it almost a specific in acute rheumatism, it exerted very little effect on diphtheria, pertussis, and typhoid, and was useless in intermittent fever.—*Boston Medical and Surgical Journal*, August 3, 1882.

EXAMINATION OF SPERMATIC STAINS. — VOGEL (*Wiener Med. Blätt.*, 1882) recommends the following method: The stain is softened with water, and in the moist condition is taken off with a knife, avoiding as much as possible the removal of any of the tissue on which it lies. A few small hairs are unimportant, however, as they are readily dissolved from the scrapings on the object-glass or slide with a drop of concentrated sulphuric acid. After two minutes one or two drops of tincture of iodine are added, the whole stirred carefully with a glass rod, and covered with a large cover-glass, which, if the dark-brown mass be too opaque, may be pressed down a little, unless it be intended to transfer smaller portions to other slides. The spermatozoa are stained distinctly brown, and are visible under the microscope in their whole contour, but it is not possible to keep the staining in longer than twenty-four hours unless the sulphuric acid be washed out, when the preparation is soon spoiled. Alcohol at once decolorizes the spermatozoa, showing the staining to be only superficial. — *Boston Medical and Surgical Journal*, August 10, 1882.

THE POISONOUS CONSTITUENTS OF TOBACCO-SMOKE. —A series of experiments has been recently conducted by Herr Kissling, of Bremen, with the view of ascertaining the proportions of nicotine and other poisonous substances in the smoke of cigars. His paper, in *Dinglers' Polytechnisches Journal*, gives a useful *résumé* of the work of previous observers. He specifies, as strongly poisonous constituents, carbonic oxide, sulphuretted hydrogen, prussic acid, picoline-bases, and nicotine. The first three occur, however, in such small proportion, and their volatility is so great, that their share in the action of tobacco-smoke on the system may be neglected. The picoline-bases, too, are present in comparatively small quantity; so that the poisonous character of the smoke may be almost exclusively attributed to the large proportion of nicotine present. Only a small part of the nicotine in a cigar is destroyed by the process of smoking, and a relatively large portion passes off with the smoke. The proportion of nicotine in the smoke depends, of course, essentially on the kind of tobacco; but the relative amount of nicotine which passes from a cigar into smoke depends chiefly on how far the cigar has been smoked, as the nicotine contents of the unsmoked part of a cigar is in inverse ratio to the size of this part—*i. e.*, more nicotine the shorter the part. Evidently, in a burning cigar, the slowly-advancing zone of glow drives before it the distillable matters, so that in the yet unburnt portion a constant accumulation of these takes place. It would appear that in the case of cigars that are poor in nicotine, more of this substance relatively passes into smoke than in the case of cigars with much nicotine; also that nicotine, notwithstanding its high boiling point, has remarkable volatility.—*Scientific American*, August 12, 1882.

THE ANTIPYRETIC ACTION OF ALCOHOL.—The conclusions drawn by DR. GREBE, from his experiments upon the antipyretic action of alcohol (*Arch. f. wiss. u. pract. Thierh.*) are as follows:

1st. The action of alcohol upon the temperature varies, according as it is given in small or large doses.

2d. In small and moderate doses alcohol, when given to animals with fever, produces an immediate slight increase in the bodily temperature, amounting to about 1° F.

3d. This increase is of short duration, and is followed by a fall of temperature to a lower level than before the alcohol was taken.

4th. In large, but not poisonous doses, alcohol depresses the temperature without any previous rise. The fall may amount to several degrees.

5th. A long-continued fall of temperature can only be obtained by giving large doses at regular intervals. Given in this manner, alcohol is a true antipyretic.

6th. Alcohol has its antipyretic effect by virtue of its power to hinder or lessen oxidation. The author states that in fever the red blood-corpuscles are diminished in number, but that by giving alcohol in antipyretic doses they reach their normal amount again. This assertion, first made by Manassein, was confirmed by Grebe.

The various theories offered to explain the heat-depressing powers of alcohol are discussed by our author. He is inclined to give the most weight to the power which alcohol has of delaying tissue-changes. Grebe's conclusions are in harmony with those of most of the other very numerous investigators in this line.—*Medical Record*, August 5, 1882.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE, ... $5.00.
SINGLE COPIES, ... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made at the risk of the publishers, by forwarding in REGISTERED letters.

Address, HENRY C. LEA'S SON & CO.,
NOS. 706 & 708 SANSOM STREET,
PHILADELPHIA, PA.

SATURDAY, AUGUST 19, 1882.

EXTIRPATION OF THE LARYNX.

NINE years ago, when Billroth, one of the most daring and brilliant of modern surgeons, announced the first extirpation of the entire larynx, we all opened our eyes and asked ourselves what next? A query he answered later by an exsection of the pylorus. The latter operation is too recent to invite determinate and especially statistical criticism. But the former operation has now been done so often that we may properly pass its cases in review, and ask ourselves what cases are suitable for it, what is the best method of doing it, and finally whether the results justify the operation.

Dr. Blum, in the *Archives Générales*, for July, 1882, has collected in a convenient brief *résumé* all the cases reported up to date, thus completing Foulis' table presented to the International Medical Congress last year. They number thirty-eight. Among them we find but one case operated on in America, and only six in England. Over twenty have been done by German surgeons, Billroth and Thiersch having each done four operations, and Czerny three. To the latter surgeon also is due the credit of the first tentative steps in the direction of the operation, for in 1870 he demonstrated its possibility on the lower animals, and even designed a canula to replace the larynx and allow of voice. Gussenbauer, however, has produced so far the best artificial larynx—a double canula, the inner one turning upwards and bearing a vibrating reed. Bruns and Czerny have modified it to advantage.

Watson, of Edinburgh, seems really to have extirpated the larynx in man in 1866, but the details of the procedure are not very explicit, and did not establish the operation as did Billroth's case seven years later.

The cases so far have been twenty of carcinoma, ten of epithelioma, six of sarcoma, one of perichondritis, and in one case the nature of the disease is not stated. Practically, therefore, the operation has been, and doubtless always will be, chiefly limited to cases of cancer and its allies; and by no means every case of these fatal diseases will be suitable for operation. So long as the disease is strictly limited to the larynx it may be amenable to operation; but once that it has invaded surrounding tissues, infiltrating them to such an extent that its limitations are uncertain, and its involvement of vessels, nerves, and other important tissues is extensive, the operation clearly would pass out of the realm of the justifiable.

Czerny has just reported in full his three cases in the *Berliner klinische Wochenschrift*. In one of them he operated five times for recurrence of the disease in less than six months, removing not only the diseased structures, but ligating and excising both jugular veins, one carotid artery and one pneumogastric nerve, and Landerer in another case had to excise one phrenic nerve.

The method is now fairly well defined, although it is still possible that improvements will be proposed in its various steps. From the very nature of the diseases requiring it, previous tracheotomy is an almost invariable antecedent condition. Any disease so serious as to demand extirpation of the larynx will almost certainly have produced such a dyspnœa as already to have required tracheotomy. Such was the fact in all these thirty-eight cases, with two exceptions. It is also a favorable condition, since the patient is then accustomed to the use of the canula, and the adhesions of the trachea prevent its ready displacement after the removal of the larynx.

During the operation, and for some eight or ten days after it, a tracheal obturator is required in order to allow the use of an anæsthetic, to keep the blood from choking the patient, and to prevent the detritus and pus from passing into the bronchi. That of Trendelenburg is the best and simplest. It is an ordinary canula surrounded by a short cylinder of rubber tied above and below. When inflated, this cylinder distends and completely fills the trachea, yet great care is required in its use, since its pressure often produces local ulceration and gangrene. After reaching the cartilage we may proceed in two ways, either with Foulis, separating the trachea and the larynx horizontally, and dissecting from below upwards; or with Pick, and most other surgeons, we may divide the thyroid vertically and remove each half separately—the simpler and safer operation. The arteries usually requiring ligature

are the crico-thyroid, the superior thyroid, and the superior and inferior laryngeal. The hemorrhage is not generally alarming, for none of the arteries are very large, and most of them may be tied before being cut, yet Czerny required twenty-seven ligatures in one of his cases. Of course, primary union is not sought for. An œsophageal tube or a large Nélaton catheter is introduced by the wound into the stomach, and left there till granulation is well established, when it may be removed and swallowing by the mouth may be tried. It is surprising in how short a time the unfortunate sufferers can use the œsophagus for this purpose. The artificial larynx may be inserted about the same time—Maurer says not earlier than the fourteenth day. In order that the epiglottis may not interfere with any such artificial larynx, experience shows that its removal during the operation is advisable, and that the tongue generally replaces it as a fender to the trachea; yet it has several times been left with good results, and Landerer advises its preservation.

What now are the results? Out of the thirty-eight cases, eighteen died within a week, and at a later period twelve more, either from the operation or an early return of the disease; only eight were alive at the time of the report, four cases of epithelioma, and two each of carcinoma and sarcoma. But in one of these cases the disease had already returned, and all the others were reported at so brief an interval after the operation as to make the ultimate results very equivocal. Bottini's case had lived without recurrence six years, Caselli's for nearly two years; none of the others for more than a year, and generally much less.

In view of these facts we may well question whether American surgeons have not done well in refusing thus far to do the operation, and in deterring others from doing it, as the sole American case certainly has. If but two or three out of thirty-eight survive for two or three years, and all the rest die, and, as a rule, much more speedily than they would if let alone, is there on the whole a gain of life or even of comfort? Are not the suffering after the operation, the mutilation, the loss of voice, the annoyance of the artificial larynx, of the œsophageal tube, and later of the troubles in swallowing, with the risk to life, and the almost absolute certainty of return with its dreadful discomforts, all taken together, well nigh prohibitory?

Cases of sarcoma seem to be best adapted to the operation, for only (mark the word) two-thirds of these cases have died. But who, as Semon says, "will take upon himself to diagnosticate early and positively carcinoma?" Or sarcoma? The forceps may remove pieces of the growth, but the microscopist cannot tell its character from so small a fragment, and the clinical history in the extreme slowness of the onset, not uncommonly extending over two to five years, the difficulty of deciding the question of the glandular involvement, and the frequent doubt as to possible syphilis, furnish too unreliable grounds for deciding so momentous a question. Some, indeed, so soon as a carcinoma is probable, or even in syphilitic stenosis, would operate out of hand—a rashness we are glad to think that is rarely found.

Dr. Cohen has justly pointed out the miserable condition of those who do not die at once, and that "survival" and "recovery" are by no means identical terms.

Czerny asks, "What would you wish to be done to yourself?" To which we reply, that if our editorial larynx were so diseased, at the proper time we would gladly undergo tracheotomy, and then live in as great comfort as we could attain, and die without the knife.

PROVISIONS AGAINST WATER CONTAMINATION.

A SOCIAL and civic problem of continually increasing importance is the preservation of the water-supply of cities and towns from contamination. It is more especially the duty of the medical profession, through their recognized organs, to expose the dangers of pollution of the potable waters, and to indicate the remedies to be adopted. It is their duty to educate the people, that the necessary legislation may be obtained, and further and more serious mischief prevented. In this country the people must necessarily be in advance of their legislators; they must have a clear conception of their needs, and then the legal remedies can be provided accordingly.

The difficulties in the way of suitable legislation to preserve the potable waters of the country from contamination, are, indeed, very great. The people are not sufficiently well informed to appreciate the nature and the sources of the danger to which their health is exposed by neglect of appropriate sanitary provisions. The sparseness of the population, and the apparent remoteness of the dangers, have influenced the well informed to regard any present precautions as superfluous. The public conscience has been lulled into a state of indifference and fancied security by the confident assertions of the chemists, that potable running waters purify themselves in the course of two or three miles. These various influences have combined against efforts to move the people to act in their own defence. This passive resistance to the proper measures, is even more difficult to overcome than active hostility.

Legislation to prevent contamination of streams and rivers supplying potable waters to cities and towns will always be opposed by certain vested

rights, by the interests of powerful corporations, and by that large body of tax-payers, who never assent to the expenditure of public money for objects which seem to them more largely æsthetical than useful. This opposition can be overcome only by the clearest evidence of pollution, and of the tremendous evils arising therefrom. Within the past few years the water-supply of Boston, Philadelphia, and New York, have alike presented obvious evidences of contamination. When the eye and the taste of the public are assailed, there is no need to appeal to the microscope and chemical tests. General apprehension as to the state of the water-supply in most of the great cities is now felt. The universal inquiry is, how far can our senses be trusted in this matter? The public mind is therefore awake, active, and in a condition of receptivity. What reply do our experts in water analysis make to the anxious inquiry? On their reply, and on the representations of the medical profession, largely depends the fate of the legislation now imperatively demanded. It needs only a reference to the remarkable differences in the results of the London analysts in regard to the condition of the water-supply of that city, to learn that the present state of chemical knowledge does not justify the confidence now expressed by chemists in their ability to define all the products of the reactions occurring in polluted water. For many kinds of impurities, the senses of sight, taste, and smell, afford more valuable information than the processes of the chemist. The mode in which organic matter is now detected is far from satisfactory. It is true, the presence of nitrates, and of ammonia, may be unerringly detected, but these are products of nature's chemical reactions; the substances out of which they are elaborated are not ascertained with a degree of certainty which does not admit of doubts—of serious doubts. It is questionable whether ordinary sewage is disposed of by oxidation, precipitation, and combinations, as is alleged, in the space of two or three miles, ordinary flow. It is certain that disease germs cannot be so disposed of, and these, without doubt, elude the highest chemical skill devoted to their discovery. Many noxious matters from dye and chemical works, minerals from mines, and other similar substances cannot be rendered innocuous by any length of stay in running water. It is obvious, that although we may obtain valuable information from chemical investigations, we ought not to rely upon them in the present state of knowledge, when it is known that various harmful substances, sewage, and disease germs, enter the water-courses. When the drainage of cities, towns, manufactories, breweries, mines, etc., flow into a river furnishing the water-supply, it may be confidently asserted that such water is contaminated to a less or greater extent, although chemical analysis may give negative results.

What then is the remedy? The English, with the practical good sense which distinguishes all their sanitary work, have early recognized the danger arising from pollution of the water-supply, and Parliament has enacted stringent measures to prevent it. Notwithstanding the comprehensive nature of these laws, they have not yet fully succeeded, and there are still loud complaints of sewage contamination, and of poisons from chemical works. But the evils of polluted water are so obvious, that Parliament will not fail to legislate effectively, if the measures now in force prove inadequate.

The legislation demanded in the interest of a pure water, is with us, State and National. Cities should be empowered by the Legislature of each State to provide against contamination of their own supply, and the National authority must be exerted when the necessary legislation includes inter-State regulations. In the absence of suitable laws to prevent contamination of potable waters, what must be the condition of the water-supply to many American cities in the course of the next half century? As populations, manufactories, and various industries increase, the streams will receive all the waste products in increasing quantity yearly, for the selfishness of men can be depended on to secure the easiest and least expensive outlet to their various excretions.

"DIRT WANTED HERE."

Such would be an appropriate motto for some of the daily newspapers. News of such a character as to be fit only for the *Police Gazette;* scandals so revolting as only to be whispered from man to man; scenes that bring blushes to the cheek, are all spread abroad in their columns for the community at large to read—men, women, children—and the unsavory mess is made to attract the more attention by large headings in displayed type. Where any crime is involved, any law broken or evaded, any evil liable to befall society, then we can understand and approve the motive which impels the exposure of even reeking filth. Moral sanitation has its parallel with hygiene. But unless there be some such reason, the needless publication of such nastiness is more than unwise; it is positively harmful to the best interests of society. What wise parent wishes his sons and daughters to become familiar with the circumstantial particulars of murders, seductions, rapes, divorces, and other such filth from the slums; or with the necessarily disagreeable details of the morgue or the dissecting-room, unless there be some overweening reason why they should be so? Sometimes, as we have said, it is necessary to publish

such stuff. But it is the frequent and the needless publication that we protest against.

We have been led to these remarks by seeing lately in the *Press* and the *Times*, of this city, two articles in point. In the *Press*, nearly a column is given up to "Sights at the Morgue—The Horrible Curiosity that moves both Men and Women—Members of the Weaker Sex willing to Coin all manner of Deceptive Stories, and even to go without their Meals, to Look Upon a Corpse;" while the *Times* fills its column with an article on "Searching for a Corpse—A Bogus Burial and the Result—How the Medical College Vaults were Scoured for the Remains of Alfred Breslow by the Dead Man's Family —An Old Ghoul's Horrible Work in the Vats." Now, even if every word of these articles were true, what good was done? Was any abuse corrected? Any social ill-tendency lessened? Any man or woman—we need hardly add any child—made wiser, better, happier, or worthier in any way? Are not the tendencies and the results of such articles purely and simply bad and degrading, lowering the moral status and defiling more or less the mind of every reader?

But there is another point from which this may be viewed, and that is the personal one. In the article in the *Times*, the search is stated to have taken place in Dr. Keen's anatomical school, and any one reading it would suppose it to have occurred within a day or two. The fact is well known in the profession that this school has been closed since March, 1875, and we learn that the event referred to occurred *eight or nine years ago*, and that the whole article is a piece of descriptive fiction. It states that the corpse was "stolen," whereas, even if the body ever were delivered there (of which there is not the slightest proof), it was delivered by the Coroner, according to law, and only a wise courtesy on Dr. Keen's part allowed any search at all. That the bodies in the "black basin" or "corpse vat" were, in turn, "gaffed with an iron hook," any doctor knows is false, while the disgusting description of the "ghoulish fisherman waist-deep among the ghastly contents of the vat," even if it were true, would mark the reporter as the "ghoul."

We have said enough of its influence on the public; but must it not also injuriously and unjustly affect Dr. Keen's standing in the community? What layman that reads it but feels a shudder and imagines that Dr. Keen countenances stealing bodes, and is a frequent spectator of such disgusting sights, instead of this being, as we are informed, the solitary instance of any such search during his ten years of teaching at the school, and that then it was done with due decorum?

The effect on anatomical science, too, is not slight. The public are naturally very jealous of dissection. The days of Burke and of the "resurrectionists" are not so far away but that they still have their weight. Should the public press, recognizing the value and the absolute necessity of dissection, make it appear as horrible and revolting as possible, and lead legislatures and people to cripple and obstruct it wherever they can? The question answers itself.

Good morals, the advancement of medical science, and personal rights, all are injured by such publications.

THE RELATIVE VALUE OF LEGAL AND MEDICAL SERVICES.

IN view of the opposition even to the moderate compensation proposed to be awarded to the physicians of the late President Garfield (for it should be remembered that no bills have ever been presented), we desire to call attention to the fees paid by the Government to the lawyers in the "Lewis Will Case."

The amount bequeathed to the Government by Mr. Lewis towards the payment of the national debt was about $1,500,000. His natural heirs contested the will. Four extra lawyers were engaged as counsel for the United States, and they *compromised* the suit at $1,000,000, and then sent in bills amounting to $105,250! The Court cut them down to an aggregate of $72,750, and this sum has just been paid without raising a murmur in Congress, where there is evidently no difficulty in appreciating the value of *legal* services, even when the Government does not gain the suit. Mr. Gilchrist (who modestly had demanded $29,000), Mr. Keasbey, and Mr. Pierrepont each received $20,000, and Mr. Parker $12,750.

We commend to members of Congress a comparison of the time, labor, skill, and responsibility involved in compromising the Lewis Will Suit and in attending President Garfield through his long and fatal illness, with the sums actually paid by the Government for professional services in the former case and proposed to be paid in the latter.

DR. JOHN BROWN.

IN the July number of *Good Words* is a short sketch of Dr. John Brown, by Rev. Dr. Walter C. Smith, which we commend to our readers as one of the most graceful and appreciative notices that we have seen. Lively, witty, admirably written, Dr. Smith's article presents Dr. Brown to us in a most life-like manner. The portrait on wood is by far the best we have seen; no one who looks on that refined and noble face can for a moment doubt that it is the index of the pure and lovely soul within.

John Brown's place in literature is assured, self-distrustful as he unfortunately was to a degree; he

has left us but little, but that little is all pure gold. Had he written nothing else than "Rab," his fame would be permanent. But "Marjorie Flemming," "Our Dogs," his sketch of his father, and of Dr. Chalmers, well show the power and the pathos, the quaint humor and the thoughtfulness of the man, the like of which blended with a style so polished and a scholarship so broad, it is not often given to us to see. Holmes of the present day, Lamb of the past, are similar spirits, yet each unlike.

If any of our readers have missed the rare pleasure of his books, let them first read Dr. Smith's sketch, and then every page that John Brown has left.

REVIEWS.

Excision of the Tongue: the Substance of a Paper Read before the Surgical Section of the International Medical Congress, held in London, 1881. Reprinted from *The Lancet*, October 22 and 29, 1881. By Walter Whitehead, F.R.C.S.E., F.R.S. Edin., etc. 8vo. pp. 18. London: J. & A. Churchill, 1881.

The author's object, in the interesting paper before us, seems to be two-fold: 1st, the advocacy of the method of removing the whole tongue, with scissors, through the mouth, for cancerous new formations; and 2d, the presentation of a plea for more accuracy in noting and reporting cases operated upon for these growths in whatever way it is done.

In both respects he has succeeded admirably. After referring to his first operation with scissors, in 1877, he describes the steps of this method, and gives a table of 28 such operations (15 by himself), with only one death as the immediate result of the operation. (Two other deaths occurred *after* the operation, but they resulted from remote causes.)

Mr. Whitehead, after considerable experience in removing the tongue by different methods, prefers the one under discussion, as being simple, easy, usually free from troublesome hemorrhage, and not liable to be followed by septic absorption. He entirely dissents from a statement of Prof. Stokes, that cutting operations for removal of the tongue are especially liable to the occurrence of hemorrhage and septic infection, saying that, from his own experience and the examination of records of over 250 cases, he should say "the danger from hemorrhage, when either the knife or scissors is used, is simply *nil*."

The use of the *écraseur* and of the galvano-cautery he opposes. Billroth's plan of ligating the lingual arteries before removing the tongue through the mouth, he thinks might be preferable to his own method, when more than the tongue was to be removed.

When the question of the actual results of operations for the removal of cancerous growths is raised, opinions are apt to differ very much. The author, speaking from cases where years of peace and immunity from apparent disease have followed *thorough* extirpation, advocates running no risk of leaving any portion of the disease behind, but to excise the whole tongue when the new tissue has attained any considerable extension.

The importance of this subject is apparent when it is considered that the deaths from cancer in England, which in 1851 numbered 5,218, numbered 12,799 in 1879, and the fact, as the author says, that "We have no reason to suppose at the present day that the internal administration of medicine, or that the topical application of drugs" (we suppose he does not include caustics), "has the smallest influence in arresting the progress of cancer; consequently, unless surgery can accomplish this, we must regard the disease as hopelessly incurable."

The pamphlet concludes with a plan for blanks, to be filled up in recording cases of excision of the tongue, which can be commended to all hospital surgeons.

CORRESPONDENCE.

THE UNIVERSITY OF LEYDEN, OLD AND NEW.

Seven years ago, February, 1875, the University of Leyden celebrated its three hundredth anniversary with a jubilee of ceremonies appropriate to such an occasion. An existence of three centuries would seem to be enough of itself to inspire a feeling of reverence, but Leyden has higher claim to fame than comes of mere survival through centuries of time. Few institutions of learning in the world can show such a distinguished roll of names among its teachers, and none has ever exerted a deeper or more lasting influence upon the minds of men. New sects of religion were founded or advocated here by Arminius and Gomar, whose followers kept up their acrimonious disputes for a century after their death, and at one time almost divided the religious world. Here lived and taught Sulmasius, and Scaliger, and Grotius, and Descartes, the same Cartesian who said that "if it be possible to perfect mankind, the means of doing it would be found in medical science," and here lived and taught, and hither flocked to hear him students from all parts of the civilized world, Herman Boerhaave, the greatest clinician of his day. A fine bronze monument to him stands just in front of the hospital grounds, looking out upon the little stream, part of the last of that classical river, the Rhine, as it winds its sluggish way to the sea, and facing a bit of landscape set off with a fine old Holland windmill, just such a picture or poem it makes as a painter might put upon canvas, or a poet into song. In the old church of St. Peter, in the town, is his tomb, on which there is an urn of black marble encircled with a wreath, and bearing upon its supporting shaft the simple inscription "*Salutifero Boerhavii genis sacrum.*" His portrait is given a prominent place among those of all the most famous professors of Leyden in the great room of the Senate, which we would call the faculty-room, of which all the guide books quote Niebuhr as saying in his Roman History that "no locality in Europe is so memorable in the history of science as this venerable hall." It is, in truth, an awe-inspiring room, not only to the green-room candidate, but to any one who has in his soul anything at all of the "spirit of discipleship." Its four walls are literally tapestried with the portraits of famous men, and a delightful relief it is, after a long contemplation of the stupid, heavy figure-heads of the nobility in the various museums, or the ecstatic zealots in the churches, to look upon these mild, benignant, faces in which the light of reason conspicuously shines.

Leyden has now only about eight hundred students (three hundred medical), but the great decline in number is due not to any declension in its attractions, but to the comparative decadence of the nation itself. At one time Holland was mistress of the seas, and was the most prominent power of Europe, after Spain, but she is now reduced, barring her Indian colonies, to a little strip of ground which she has to continually fight the sea to maintain, and which we might say, being mostly below its level, properly belongs to the sea. So the Dutch language is spoken over a very limited sur-

face of the earth. Nobody outside of Holland cares to learn it, and hence, as all instruction here is imparted either in Dutch or in Latin, which is being less used every day, the students of Leyden are pretty much all from Holland. Moreover, Holland has several other universities, at Gromingen, at Amsterdam, at Utrecht, each of which draws its proportion of students away from Leyden. So far as concerns the "inducements," or, as the college circulars say with us, "the facilities," of instruction, they are better in Leyden than ever before. There may be a larger, but there is not in Europe a finer, collection than is found in the Museum of Natural History, nor is there anywhere a finer, or better arranged, or better sustained museum of comparative anatomy. The clinical departments were never as large or as well conducted as now, and the cost of living, which our college circulars never fail to mention, is reduced to figures which might be anticipated in a city with houses enough for 100,000 inhabitants, its population once, reduced to 40,000, its population now. There is, hence, a corresponding "freedom from temptation," this for the benefit of the academic department (medical students being everywhere safe), as it would be hard to find a place so thoroughly invested with the "holy calm" of academic shades.

Of the museum of anatomy, I have already made mention, but something more than mention should be made of such a rich and varied cabinet. It is embraced in three large rooms whose centres are covered with tables, and whose walls are lined with cases containing the specimens, all under glass. The osteological specimens are perfectly white, the fine macroscopic (not microscopic) shavings showing the architecture of bone, being as thin as paper, and as white as snow. Of the wet specimens, I may say that I saw none that were not perfectly clear, and this fact bespeaks a care in original preparation which curators and prosectors will understand. The section illustrative of embryology and teratology is singularly fine, and the pathological collection of scoliotic skeletons is almost unique. Among the curiosities I was shown the epidermis of nearly the entire hand of an infant, a flake or two being lacking from the palmar surface; and, among the calculi, an enormous phosphatic stone nearly as large as the fist, with one end in cauliflower excrescence, like spiculæ of newly-fallen snow, and one large calculus about the size of a hen's egg, quite as long but not more than half as thick, removed by the patient himself with the knife, an old shoe-knife, and was informed that the patient lived after the operation, which was supra-pubic, of course, for twenty-three years.

Having noticed that the plants in the botanical garden were arranged after the system of Linnæus, who taught here once, by the way, though not in the University, I had the curiosity to ask the prosector of anatomy what theory of development was taught here now. "Why," he said, with a smile, "no anatomist, now-a-days, teaches any other theory than that of Darwin."

J. T. W.

LEYDEN, JULY 15, 1882.

"PROFESSIONAL POACHING."

To the Editor of THE MEDICAL NEWS.

SIR: The discussion of the New York Code of Ethics, in your valuable journal, has presented the new departure in its true relations to the profession and laity. And now, while the Saratoga season is upon us, and we are moving amid its varied pleasures and experiences, may I trespass upon your columns with some reflections upon matters professional, in the light of the new and revised edition of this ethical gospel of peace, as set forth in one of its phases in February last. The sentiment of the profession has been emphatically expressed in many quarters in regard to this "progressive liberality" of the New York State Medical Society. There was, however, another feature developed at that meeting, having wider scope in its "liberality," and being more radical a "reform" than the changes in the Code which were at last adopted. We refer to the resolution offered by Dr. Roosa, which received the sanction of the majority of members voting; the vote being significant as a manifestation of the opinion of some in regard to the existing Code, and possibly in regard to a necessity for the existence of any code whatever. The resolution embodied the following: "That the only ethical offences for which they (the profession) claim the province to exercise the right to discipline are those comprehended under the commission of acts unworthy of physicians and gentlemen." Also, "That we enjoin the County Societies and other organizations in affiliation with us, that they strictly enforce the requirements of this Code."

The reported vote upon this was 39 in favor and 37 against, and, as it was considered by the President an amendment to the by-laws requiring a two-thirds vote, it was declared lost. In the light of such sentiment, we rise, Mr. Editor, to make inquiry. A few years ago questions of ethics were discussed in a prominent medical journal relative to the position of *metropolitan* and *rural* practitioners (as they were editorially termed) at places of summer resort. Now, it may be comfortable to leave the *metropolis*, and, straying out into the nooks and corners of the country, to pick up crumbs of professional experience that will meet the expense of summer travel and the demands of the landlord. The wearied metropolitan may find rest and refreshment in the process, and may add to his physical condition a muscular tone which will help him cheek it through if disturbed by reflections upon the mode and manner of his professional poaching. He may gain the ear of the hotel proprietor, and insinuatingly suggest the advantage it may be to the house to have him around, and he may seek acquaintance with each newly arrived guest, incidentally making mention of his metropolitan origin, and making the position more sure by the presentation of his professional card. The palm of the Ethiopian hall-boy may be impressed by a percentage on every professional call he may bring to the waiting practitioner, or the local paper may announce the arrival at the fashionable hotel of —— M.D., where he is to pass the season. The calculating practitioner may visit his professional brethren in the various cities and prepare the way for business by announcing the fact that he will be located thus and thus during the summer months, and patients may be referred to him while he rusticates amid the pleasures of his country surroundings. The patient may travel in search of improvement, bearing in his pocket the letter from his family physician that refers him to —— M.D., who will be found sojourning at some first-class hotel for *the season*, and when the crowd have departed, the harvest has passed, and the pickings grown poor, the sojourning M.D., will return to his house and home, waiting the coming of another season, when he again may seek rest, refreshment, and additional practice. We paint no imaginary picture, and in the light of experience, Mr. Editor, rise to the inquiry, where in all this is the code of the gentleman? Are these practitioners within the code as pictured by the genial Roosa? Had this liberal code been adopted (and from the vote there seemed not a few who favored it), how were such gentlemen to be reached?

The second clause of the resolution enjoins upon County Societies, that they strictly enforce gentlemanly requirements, and we inquire how and in what way could a county society enforce upon these wandering practitioners gentlemanly requirements which they so

instinctively and so industriously ignore? As these gentlemen are practising in Saratoga County, is it within the province of the Saratoga County Medical Society to exercise the right of gentlemanly discipline? or would these nomadic professionals be amenable to some other Society, which shall teach them professional courtesy? They are legally qualified as practitioners, if not ethically qualified in the manifestation of exemplary traits of gentlemanly character, and one could hardly expect, on their part, any especial regard for ethical considerations, whether embraced under the existing Code or that proposed by Dr. Roosa. County Societies might find it a weighty task sustaining the privileged position of interpretation of gentlemanly acts and enforcement of gentlemanly discipline. Timothy Titcomb, in one of his essays, remarks: "It seems to me, either there is a great deal of human nature in a pig, or that there is a great deal of pig in human nature;" and we are glad the resolution did not prevail in this view of our professional relations during the harvest of a Saratoga season.

NEWS ITEMS.

LONDON.

(*From our Special Correspondent.*)

The Royal College of Physicians on Medical Advertising.—The Fellows of the Royal College of Physicians of London met in solemn conclave last week to consider a resolution condemning advertisements of medical books in the lay press, and the giving of medical testimonials to the proprietors of mineral waters, medicinal preparations, etc. An animated discussion ensued, and ultimately the following resolution was passed: "That the system of extensively advertising medical works, and the custom of giving laudatory certificates of medicinal and other preparations and medical and surgical appliances, whether for publication or not, is misleading to the public, derogatory to the dignity of the profession, and contrary to the traditions and resolutions of the Royal College of Physicians."

It was pointed out that extensive advertising in the medical press was deceptive, as tending to associate special names with particular diseases. An interesting feature of the debate was the confession by a distinguished physician that he received five guineas for a certificate praising a "favorite natural aperient." We now know the value of the much-advertised recommendations of this water.

An Easy Method of Detecting the Bacillus Turerculosis for Diagnostic Purposes.—The corroboration of Dr. Koch's discovery of a *Bacillus tuberculosis* has been attempted by several histologists in London; and at the Laboratory of the Brown Institute in particular considerable labor has been expended in this direction, which has not met with success. Dr. Heron has obtained the bacillus by Ehrlich's process, but with this exception the specimens that have been used to demonstrate this newest "germ" have been imported from Germany. Now, however, one of our best microscopists, Dr. Heneage Gibbes, who has been remarkably successful in multiple staining, has hit upon a simple, and, he says, certain, method of detecting this bacillus, and one which brings it out so clearly that it can be demonstrated by a common microscope with only one-quarter inch objective, and no special means of illumination. The colors used are magenta crystals and chrysoidin; the latter is a brown, which does not stain the ground substance so intensely as vesuvin. They can be procured from the Badesche Anilin Fabrik, 22 Bush-lane, Cannon Street, E. C. The following are the formulæ he has used: Two grammes of magenta crystals, three grammes of pure anilin, twenty cubic centimetres of alcohol, specific gravity .830, twenty cubic centimetres of distilled water. Dissolve the anilin in the spirit, and then rub up the color with it in a glass mortar, adding the spirit gradually until it is all dissolved, then add the water slowly, while stirring, and keep in a stoppered bottle. Make a saturated solution of chrysoidin in distilled water and add a crystal of thymol to make it keep; a dilute solution of commercial nitric acid is made, one part of acid to two of distilled water. For sputum, the following process is the most simple: Spread a thin layer on a cover glass and let it dry; when quite dry pass it two or three times through the flame of a small Bunsen burner, and let it cool. Filter two or three drops of magenta solution in a watch glass, place the cover glass with the sputum downwards on the stain, taking care there are no air bubbles under it. Let it remain for fifteen or twenty minutes, then wash in the dilute acid until all color has disappeared; remove the acid with distilled water, when a faint color will return; then place the cover glass in the same manner as before on a few drops of chrysoidin filtered into the bottom of a watch glass, and let it remain a few minutes until it has taken on the brown stain; wash off the superfluous color in distilled water, and place the cover glass in absolute alcohol for a few minutes; remove and dry perfectly in the air; place a drop of Canada balsam solution on the cover glass and mount. Sections of hardened tissue are treated in the same manner with the necessary modifications.

EDINBURGH.

(*From our Special Correspondent.*)

Edinburgh University.—Mr. John Chiene, M.D., F.R.C.S. Ed., has been appointed by the curators to succeed the late Professor Spence in the chair of surgery. Mr. Chiene is a graduate of this university, and for four years immediately after obtaining his degree assisted Goodsir, and latterly Turner, in the anatomical department. He is thus an excellent anatomist, and this is further assured by the fact of his having held for several years the position of Examiner in Anatomy for the University degree. On leaving the Anatomical Department he commenced the practice of surgery in the city, working for the most part under the auspices of Professor Lister, who strongly advocated Mr. Chiene's claims for the chair. He was also intimately associated with Lister in his hospital work, and since that distinguished surgeon went to London, Chiene has been regarded as the principal exponent in Edinburgh of antiseptic surgery. Perhaps upon this ground more than any other, was Chiene selected to succeed Spence; and it is fitting that Edinburgh, as the birthplace of antiseptic surgery, should thus prominently acknowledge its merits. Mr. Chiene, although a young surgeon, has found time to greatly enrich the literature of both surgery and anatomy. He is the author of an excellent work on "Surgical Anatomy," and recently contributed to the "American Practitioner" a series of lectures on the "Elements of Surgery," which show how well he has grasped the principles of the Listerian treatment. His papers on "Healing by Blood-clot," and on "Bacteria in Healthy Organs" illustrate the originality of his mind and his extensive acquaintance with other branches of medicine, as well as those of surgery and anatomy. Mr. Chiene has also proved himself a most successful and enthusiastic teacher in the extra-mural medical school.

VIENNA.

(From our Special Correspondent.)

PROF. HERMANN NOTHNAGEL.—The following notice appeared recently in one of the Vienna newspapers:

"His Royal and Imperial Apostolic Majesty has been most graciously pleased, through his most high resolution of July 11, to call Dr. Hermann Nothnagel, Professor in the University of Jena, to be Regular Professor of Special Pathology and Therapy and of the Medical Clinic in the University of Vienna.

"CONRAD EYBESFELD,
"Minister of Education."

The selection of Prof. Nothnagel as Duchek's successor is very cordially received by professors, teachers, students, and the medical press in Vienna. The fact that Baron Conrad Eybesfeld, Minister of Education, did not allow himself to be influenced by the politicians, who were working for the interests of local candidates, is generally recognized. Prof. Bamberger, for some time past, has been in feeble health, and this circumstance has probably led to the sudden and entirely unexpected appointment of Prof. Nothnagel.

While, upon the one hand, Prof. Nothnagel, as Professor of the First Medical Clinic in the "Allgemeine Krankenhaus," will occupy the same position which ten years ago Oppolzer and Skoda held, and must thereby recognize in the appointment reward for his great work; on the other hand, the Faculty of Medicine of the University of Vienna must congratulate itself upon the acquisition of a man who will restore to the school the prestige in clinical medicine which has gradually been lost through the development of the so-called "specialties."

Prof. Nothnagel was born September 28, 1841, in Alt-Sutzeporche, a small village near Berlin. He was the son of a physician. His gymnasial studies were completed in Königsberg in the Neumark; his medical studies, occupying the years 1859–1864, were pursued at the University of Berlin. He passed a brilliant examination before the State Board in the winter of 1864–'65, after he had obtained his degree of Doctor of Medicine on August 6, 1863.

The instructors who are especially to be named as influencing the formation of Nothnagel's medical character are Virchow and Traube. Traube was especially interested in his student, and remained in intimate friendship with him until his death.

In 1865 Dr. Nothnagel went to Königsberg, in Prussia, as the assistant of Leyden, when, in 1867, he became Privat-Docent, and taught auscultation, percussion, laryngoscopy, and electro-therapy. Leyden's influence led him to the study of nervous diseases, and this period may be regarded as the starting-point of his scientific life. In 1868–1870 he was a Privat-Docent in Berlin. In 1870 he transferred himself to Breslau in a similar capacity. In the same year his remarkable "Handbook of Therapeutics" appeared in Berlin; in 1874 the second, and in 1880 the fourth edition of this admirable work appeared. In Leipzig, in 1872, an essay upon the "Epileptic Seizure" attracted deserved attention. After two years' work in the University of Breslau, Dr. Nothnagel accepted a call, in the fall of 1872, as regular Professor of Therapeutics and Pharmacology in Freiburg, when he had charge of the Poliklinik, while Kussmaul was Professor of the Clinic.

In the summer of 1874 two professorships were offered to him at the same time—one in Zürich, made vacant by Biermer's departure: and one in Jena. He accepted the less brilliant position in Jena, in which city he has most zealously worked since his appointment. In 1875 and 1876 appeared his "Magnum Opus," "Handbook of Diseases of the Nervous System," consisting of two volumes, of which the one was edited by himself, in connection with Eulenberg, Ziemssen, Jolly, and J. Bauer; the other with the assistance of Obernier, O. Heubner, G. Huguenin, and E. Hitzig. Both volumes will be found in Ziemssen's "Handbook of Special Pathology and Therapy." Minor essays are contained in R. Volkmann's collection of clinical papers. Among them may be mentioned "Neuritis, in a Diagnostic and Pathological Point of View" (Leipzig, 1876); "Symptomatology of Intestinal Ulceration" (Leipzig, 1881). "The Influence of Opium upon the Intestinal Tract" has recently appeared in Virchow's Archives. One of his chief works is undoubtedly "The Topical Diagnosis of Diseases of the Brain" (Berlin, 1879).

PROF. V. LANGENBECK.—Langenbeck has resigned from the Berlin Medical Society, of which he has been a member since its foundation. Becoming ceremonies will be celebrated in honor of the retiring surgeon in Wiesbaden.

PROF. VOLKMANN.—Prof. Richard Volkmann has declined Langenbeck's Chair of Surgery in Berlin, and remains in Halle. The citizens of Halle are perfectly jubilant over the declination, as it certainly indicates a high regard for the honor and fame of the university of that city.

SUCCESSOR TO LANGENBECK.—Prof. Bergmann, in Würzburg, Prof. König, and Prof. Czerny were proposed as candidates for the vacant Chair of Surgery in the University of Berlin. Prof. v. Bergmann was elected.

LIGATURE OF THE INNOMINATE ARTERY.—MR. THOMSON'S patient died on Thursday, July 20, the forty-second day after ligature of the innominate artery. There was no recurrence of bleeding after the thirty-ninth day. The sinus was found to terminate in an ulcer, which involved the anterior wall of the junction of the innominate, carotid, and subclavian arteries. The innominate and carotid were filled with clot; the subclavian contained a clot occluding it to the extent of half an inch. The position of the ulcer was on the distal side of the ligature, the constricted portion of the innominate not being involved. The hemorrhage had apparently taken place from the innominate, as there was a recent blood-stain on the cardiac side of the clot. None of the vessels were pervious to water forced in with a syringe. The aorta was atheromatous. Consolidation was proceeding satisfactorily in the tumor. Excluding the successful case of Dr. Smith, of New Orleans, this is the second longest survival on record, Graefe's case having reached the sixty-seventh day, and Cooper's the thirty-fourth.—*British Medical Journal*, July 29, 1882.

GASTROSTOMY.—MR. LANGTON has recently performed this operation at St. Bartholomew's Hospital on a young child. The patient was suffering from a stricture of the œsophagus, produced by having swallowed a quantity of potash lye about six months earlier. The patient was seen at the consultation on June 22d, and Mr. Langton was then supported by his colleagues in the determination to attempt to relieve the child, who was nourished solely by enemata, by opening the stomach. Under these circumstances, the first part of the operation was performed on June 24th; and five days later the stomach was opened, and a soft tracheotomy tube introduced. The patient recovered well from the operation, and there was no general peritonitis; but it gradually sank, and died of exhaustion a week after the gastric fistula was first used for the introduction of food.—*Brit. Med. Journ.*, July 15, 1882.

A NEW AND CHEAP DISINFECTANT.—Dissolve half a drachm of nitrate of lead in a pint of boiling water; also two drachms of common salt in a bucket of water;

pour the two solutions together; allow the sediment to precipitate, and the clear supernatant fluid will be a chloride of lead. This will deodorize and disinfect sinks, water-closets, or drains, and a cloth dipped into it will sweeten a fetid atmosphere.—*Dublin Medical Journal*, May, 1882, from *Australasian Medical Gazette.*

Threatened or Actual Epidemics.—The Supervising Surgeon-General of the U. S. Marine-Hospital Service, under date of August 9, 1882, has issued a circular to Medical Officers of the Marine-Hospital Service, and officers of State and Municipal Boards of Health, informing them that Congress, at its last session, enacted that

"The President of the United States is hereby authorized, in case of a threatened or actual epidemic, to use a sum not exceeding one hundred thousand dollars, out of any money in the Treasury not otherwise appropriated, in aid of State and local boards, or otherwise in his discretion, in preventing and suppressing the spread of the same."

He further informs them that the President has decided to employ this contingent appropriation through the agency of the Treasury Department, and that, in case of a threatened or actual epidemic, immediate action will be taken, upon application from the Governor of a State addressed to the Secretary of the Treasury.

The attention of Medical Officers of the Marine-Hospital Service is called to the following paragraphs of the regulations governing this service, approved by the Secretary of the Treasury November 10, 1879:

Paragraph 61.—"Medical Officers and Acting Assistant Surgeons of the Marine-Hospital Service will inform themselves fully as to the local health laws, and the regulations based thereon and in force at their respective ports and stations, and will comply strictly therewith."

Paragraph 62.—"Medical Officers and Acting Assistant Surgeons are, under the direction of the Supervising Surgeon-General, required to observe and to aid in executing the quarantines and other restraints established by the health laws of any State, and to report forthwith to the said Surgeon-General any important event or fact that may come to their knowledge bearing upon the importation, outbreak, or spread of cholera, yellow fever, small-pox, typhus, or other epidemic disease, at or near their respective stations."

Immigrant Inspection Service.—Dr. John H. Rauch, supervising inspector in the Illinois district, submits the following report for the month of July, of the operations of the Immigrant Inspection Service, N. B. H., in the district under his supervision.

During the month an aggregate of 21,000 immigrants were inspected by the assistant inspectors, who found about sixteen per cent. of these unprotected, liable to contract small-pox and to propagate the disease. The necessary precautions were taken with all of these cases, as well as with one case of varioloid found in transit, and several convalescents, one being an immigrant removed from a train and treated in the small-pox hospital at Rochester during the month of June.

Although there is a marked improvement in the character of the protective work done on shipboard, as compared with that noted on beginning inspections, this is by no means uniform, as is seen by the following extracts from the assistant inspectors' notes of careless, imperfect or neglected vaccinations and revaccinations:

Steamship *Republic.*—"Practically worthless; no adult vaccination."

Strasburg.—"Very poor; only eleven successful out of 340 vaccinations—result evidently due to want of care on part of steamship surgeon."

General Herder.—"None showed successful vaccination."

Hermann.—"Only thirteen properly protected out of 410; the vaccination performed on shipboard very unsatisfactory. All passengers provided with *protection cards.*"

The *Strasburg* and *Hermann* are regular Baltimore packets, and the latter, at least, is known to have been the means of introducing small-pox into five localities in Illinois during the past spring.

It might be profitable to inquire to what extent such vessels and the neglect of their surgeons are responsible for the present prevalence of small-pox in Baltimore.

On July 28, among the passengers by the steamer *Erin*, were found ten convalescents who had had small-pox within a month before leaving Ireland.

Notwithstanding that the aggregate number of inspections was less in July than in the preceding month, the relative number is much larger. Immigration has probably fallen off one-half since May last, and it is believed that of the total number now arriving, very few find their way into Illinois or cross the State without being subjected to one or more rigorous inspections. The reports of small-pox outbreaks in the region west of the Mississippi River have been notably less during July, while in this State there has not been a single case reported during the month, outside of Chicago. The following table shows the steady decline of the disease in that city:

Month.	Cases Reported.	Deaths.
April,	321	92
May,	281	65
June,[1]	124	29
July,	44	11

At the close of the month there were only ten cases under treatment in the city, and one in the State at large.

In other districts of the service it is observed that increased familiarity with the work has secured increased efficiency, and thus materially lightened a labor which was found to be very onerous during the first month. For example: the vaccinations found to be necessary among passengers arriving over the Grand Trunk road in June were very nearly 36 per cent. of the total inspections. During July, owing to the increased number of vaccinations at Port Huron, Mich., this percentage has been reduced to 8.3 per cent.

Many cases of cholera infantum, measles, and whooping-cough are met with by the inspectors, who, so far as time and opportunity serve, render such medical assistance as is necessary.

The railway service has continued to afford every desired facility to the inspectors, and, aside from the advent of an occasional unannounced train over a connecting line, every emergency has been promptly met. The coaches for immigrant passengers are kept in good sanitary condition, and the general welfare of these people seems to be consulted on business principles.

From June 1st to July 31st there were 47,948 inspections, and 7799 vaccinations.

Health in Michigan.—Reports to the State Board of Health, for the week ending August 5, 1882, indicate that cholera morbus, cholera infantum, and diarrhœa, have considerably increased, that puerperal fever has increased, and that tonsillitis and whooping-cough have decreased in area of prevalence.

It appears that the increased prevalence of cholera

[1] Inspections began June 1.

morbus, cholera infantum, and diarrhœa was coincident with a high temperature, a great increase in relative and in absolute humidity; also with a low atmospheric pressure, and a considerable reduction in the day ozone.

Including reports by regular observers and by others, diphtheria was reported present during the week ending August 5th, and since, at 20 places, scarlet fever at 8 places, measles at 11 places, and small-pox at 17 places, as follows: in Deerfield township, Lapeer Co., July 30; at Lansing (one case, convalescent), July 31; in Crystal township, Montcalm Co. (4 cases), August 1; in Rapid River township, Kalkaska Co. (4 cases), in Orange, in Sebawa, in Danby, Ionia Co., and in Mancelona township, Antrim Co. (3 cases), August 3; at Mt. Morris, Genesee Co. (one case, convalescent), August 4; at Detroit (3 cases), Flint, and Portland (one case), August 5; in Walker township, August 7; at Grand Rapids, August 9; at Clio, Genesee Co., in Ionia township, and near Carson City, Montcalm Co., August 10.

PROF. V. LANGENBECK, on July 24th, on the occasion of his retirement from the Professorship of Surgery, had the compliment of a brilliant reception and collation tendered him by the students of Berlin.

THE BRITISH MEDICAL ASSOCIATION held its Fiftieth Annual Meeting at Worcester, August 8, 9, 10, and 11. The programme shows good scientific work in the eight sections. The Address in Medicine will be delivered by Dr. Wade, of Birmingham, the Address in Surgery by Dr. William Stokes, of Dublin.

Dr. Austin Flint, of New York, will read a paper in the Medical Section on the Self-limited Duration of Pulmonary Disease.

We hope to promptly lay before our readers a full account of the meeting, from our Special Correspondent.

PRIZE OF THE ACADÉMIE DE MÉDECINE AWARDED TO DR. H. J. BIGELOW.—The prize of 10,000 francs founded by the Marquis d'Argenteuil, granted every six years to the author publishing the most important advance in urinary surgery, has been divided between Dr. Henry J. Bigelow, for his work on The Treatment of Strictures of the Urethra by *dilatation urodyname*, and Dr. Th. Anger, for his essays on New Thermo-Cautery, Lithotomy Instruments, and Peno-scrotal Hypospadias. Dr. Bigelow receives 6000 francs and Dr. Anger 4000 francs.

OBITUARY.—The *British Medical Journal* announces the death of PROF. F. M. BALFOUR, in Switzerland, from a fall in the Alps.

Francis Maitland Balfour, the recently elected Professor of Animal Morphology in Cambridge, was born in 1851, received his early education at Harrow, and received his degree at Cambridge, where, even as an undergraduate, he distinguished himself by important embryological work. After graduation he went to the Zoölogical Station, at Naples, and there collected the material for his valuable memoir on the Elasmobranchs. He was elected Fellow of the Royal Society, in 1878, and in November obtained the high distinction of a Royal Medal, and in 1880, he received the degree of LL.D. from the University of Edinburgh. He was the author of a multitude of miscellaneous papers on embryology and comparative anatomy, and of the best text-book extant on comparative embryology.

—— On the 13th of July, JOSÉ LAURENÇO DA LUZ, the Portugese surgeon, said by the *O Correio Medico de Lisboa* to have been the peer of Dupuytren and Astley Cooper. Da Luz was Professor of Surgery and Director in the Medico-Chirurgical College of Lisbon, and the founder of the first medical journal published in that city, the *Jornal da Sociedade das Sciéntias Medicas*, to which he contributed a number of valuable articles.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT, U. S. ARMY, FROM AUGUST 8 TO AUGUST 14, 1882.

PROMOTIONS.

Colonel CHARLES H. CRANE, Assistant Surgeon-General, promoted Surgeon-General, with the rank of Brigadier-General, to date from July 3, 1882, *vice* Barnes, retired.

Lieutenant-Colonel CHARLES C. KEENEY, Surgeon, to be Surgeon, with the rank of Colonel, June 30, 1882, *vice* Cuyler, retired.

Lieutenant-Colonel JOHN F. HEAD, Surgeon, to be Surgeon, with the rank of Colonel, June 30, 1882, *vice* King, retired.

Major JOSEPH B. BROWN, Surgeon, to be Surgeon, with the rank of Lieutenant-Colonel, June 30, 1882, *vice* Simons, retired.

Major DAVID L. MAGRUDER, Surgeon, to be Surgeon, with the rank of Lieutenant-Colonel, June 30, 1882, *vice* Keeney, promoted.

Major CHARLES PAGE, Surgeon, to be Surgeon, with the rank of Lieutenant-Colonel, June 30, 1882, *vice* Head, promoted.

Captain JOHN BROOKE, Assistant Surgeon, to be Surgeon, with the rank of Major, March 2, 1882, *vice* Frantz, deceased.

Captain WM. H. GARDNER, Assistant Surgeon, to be Surgeon, with the rank of Major, June 23, 1882, *vice* Notson, deceased.

Captain CHARLES SMART, Assistant Surgeon, to be Surgeon, with the rank of Major, June 30, 1882, *vice* Brown, promoted.

Captain WM. S. TREMAINE, Assistant Surgeon, to be Surgeon, with the rank of Major, June 30, 1882, *vice* Magruder, promoted.

Captain MORSE K. TAYLOR, Assistant Surgeon, to be Surgeon, with the rank of Major, June 30, 1882, *vice* Page, promoted.

HARTSUFF, ALBERT, *Major and Surgeon.*—Having reported at these headquarters on 3d inst., surrendering unexpired portion of his leave of absence, will proceed to Fort Union, New Mexico, and report to the commanding officer for duty.—*S. O. 153, Department of the Missouri, August 4, 1882.*

BROWN, J. M., *Major and Surgeon.*—Assigned as Attending Surgeon at headquarters Department of the South, in addition to his duties as Post Surgeon at Newport Barracks, Kentucky.—*S. O. 79, Department of the South, August 10, 1882.*

WILCOX, F. E., *Captain and Assistant Surgeon.*—To accompany Troop F, First Cavalry, to Fort Walla Walla, and then repair to these headquarters for assignment to duty at Vancouver Barracks.—*S. O. 106, Department of the Columbia, July 31, 1882.*

TAYLOR, M. E., *Captain and Assistant Surgeon.*—Relieved from duty at Jefferson Barracks, Missouri, and to report by letter to the Surgeon-General.—*S. O. 185, A. G. O., August 10, 1882.*

POWELL, J. L., *First Lieutenant and Assistant Surgeon.*—Confirms telegraphic instructions of this date to allow the Lieutenant-Colonel Tenth Cavalry, and Troops G and L of that Regiment, and Assistant Surgeon Powell to continue temporarily, and until further orders, at Fort Stockton, Texas.—*S. O. 84, Department of Texas, August 9, 1882.*

MCCREERY, G., *First Lieutenant and Assistant Surgeon.*—Transferred from Fort Apache to Whipple Barracks, Arizona Territory.—*S. O. 119, c. s., Department of Arizona.*

TILERT, R., *First Lieutenant and Assistant Surgeon.*—Relieved from duty at Fort Walla Walla, Wyoming Territory, to accompany Troop E, First Cavalry, to Boise Barracks, and, on arrival there, relieve Assistant Surgeon Wilcox from duty at that post.—*S. O. 106, c. s., Department of Columbia.*

RAYMOND, H. I., *First Lieutenant and Assistant Surgeon.*—Transferred from Whipple Barracks to Fort Apache, Arizona Territory.—*S. O. 119, Department of Arizona, August 3, 1882.*

EGAN, P. R., *First Lieutenant and Assistant Surgeon.*—Relieved from duty at David's Island, New York, and to report in person to the Commanding General Department of Arizona for assignment to duty.—*S. O. 185, c. s., A. G. O.*

WIKEMAN, WM. J., *First Lieutenant and Assistant Surgeon.*—Relieved from duty at Columbus Barracks, Ohio, and to report in person to the Commanding General Department of the Platte for assignment to duty.—*S. O. 185, c. s., A. G. O.*

THE MEDICAL NEWS *will be pleased to receive early intelligence of local events of general medical interest, or of matters which it is desirable to bring to the notice of the profession.*

Local papers containing reports or news items should be marked.

Letters, whether written for publication or private information, must be authenticated by the names and addresses of their writers—of course not necessarily for publication.

All communications relating to the editorial department of the NEWS *should be addressed to No. 1004 Walnut Street, Philadelphia.*

ORIGINAL LECTURES.

PECULIAR FEATURES OF PNEUMONIA IN YOUNG CHILDREN.

A Clinical Lecture,

BY W. J. CONKLIN, M.D., OF DAYTON, OHIO,

PROF. OF DISEASES OF CHILDREN IN STARLING MEDICAL COLLEGE.

GENTLEMEN: Within the past few weeks you have seen, in the clinic-room, all of the forms of acute lung disease commonly observed in the young. To-day I have the exceptional opportunity of showing you one of the rarer forms—a pneumonia of the apex.

This little boy, fourteen months old, whose history you have just heard, is suffering from a well-marked croupous pneumonia, limited to the upper lobe of the right lung. Using these cases as a text, it may be profitable for us to devote this hour to the consideration of the pneumonias of early life, with a view of bringing into stronger relief the pathological and clinical differences which the age of the patient stamps upon the disease. The importance of a thorough knowledge of this class of diseases will be appreciated when you remember that fully one-third of all deaths under five years of age depends upon some lesion of the respiratory organs. Jacobi estimates that forty per cent. of the deaths during the first year of life is due to diseases of the digestive, and twenty per cent. to those of the respiratory, system; in the second year the relative proportion is changed, and thirty-six per cent. of the deaths is due to lesions of the respiratory, while only nine per cent. to those of the digestive, organs. Thus stomach and intestines are the broad avenues to death during the first, and bronchi and lungs during the second, year of life. The practical deduction from these figures is that the respiratory organs are better protected during the first year; for unquestionably the tendency to disease and death through the respiratory system is strongest during the early months of life, and steadily diminishes up to puberty. The environments of the infants—the absence of exciting causes—are sufficient to account for the immunity of the early months. We need not dwell upon these points, but certainly the senseless, if not cruel decrees of fashion, in regard to dress, are largely responsible for the frequency of lung troubles in young children. Life and health stand for nothing compared with show. The complacency is refreshing with which a mother will gush over the bare legs and exposed bust of her yearling child, while she robes herself in seal and fur.

In children, as in adults, we meet with two forms of acute pneumonia, but the comparative frequency with which they occur varies greatly at the different periods of life. Lobar or croupous pneumonia is preëminently a disease of adult life, while the lobular or catarrhal form is peculiarly the pneumonia of infancy. In a child under five years of age the presumption is strongly in favor of the catarrhal form, but I am positive that lobar pneumonia is by no means so unfrequent, even in infancy, as many authorities would lead us to infer. As you know, it is not very unusual to meet even nurslings in our dispensary practice suffering from lobar pneumonia.

Squire, of London, reports several cases which came under his observation; Steinitz gives the histories of eighty-four cases which occurred in his clinic at Breslau; and Ziemssen, of Berlin, records one hundred and eighty-six cases, of which one hundred and seventeen occurred in the first six years, and sixty-nine in the succeeding ten years of life. Juergensen, after alluding to the difficulties of diagnosis in children, makes the statement that many who are reported to have died from "teething," "worms," "convulsions," etc., have really succumbed to an unrecognized lobar pneumonia.

Lobular pneumonia is in fact a capillary bronchitis plus an affection of the air-cells, and is happily named broncho-pneumonia. It never occurs as a primary lesion, but is always secondary to a bronchitis or to those specific diseases, as measles and pertussis, in which bronchial catarrh is a part of the natural history. It is also intimately associated with certain diatheses, as rickets and scrofula.

The conditions which render a bronchitis so much more serious in early than in adult life, largely hinge upon the smaller sizes of the bronchioles. To reduce the calibre of a bronchus in an adult by its thickened mucosa and the adhesion to its walls of tough mucus, will only slightly interfere with its function as a carrier of air, but in the smaller tube of the child it means occlusion, more or less complete, with resultant dyspnœa, lobular collapse, and perhaps pneumonic infiltration.

Collapse of the lobules of the lung, which is such a common complication of bronchitis in children, plays an important role in the development of catarrhal pneumonia. Many authorities hold it to be absolutely essential that collapse of one or more pulmonary lobules should precede the inflammation of the alveoli. In this event, the links of the chain are bronchitis, plugging of a bronchus by swollen membrane and mucus, collapse of lobule, and, finally, the setting up in the collapsed portion of an inflammatory process similar to, but not identical with that of croupous pneumonia. Others, while admitting that this is the usual sequence, maintain that the collapse is not essential, and that the inflammation often travels along the successive branches of the bronchial tree, and thus invades the air-cells. The balance of proof is undoubtedly in favor of the view that pulmonary collapse is the very frequent, but not necessary, antecedent of the pneumonia.

It is estimated that one-sixth of the illnesses, and about the same proportion of deaths, in children under five years of age, are due to catarrhal diseases of the respiratory organs. But lobular pneumonia possesses intense clinical interest not only on account of its fatality, but also for the reason that it is recognized as the chief factor in the etiology of caseous phthisis. Under favorable circumstances, the epithelial cells and leucocytes which crowd the bronchioles, alveoli, and intervening connective tissue, undergo a conversion into fat and are absorbed, or into mucus and are expectorated. But if anything occurs to arrest these processes; if the constitution be vulnerable from inheritance, previous disease, or bad surroundings, the inflammatory product becomes converted into a caseous mass, which mechanically compresses air-cells, bronchioles, and blood-vessels until they die, and then the child has so-called caseous phthisis. Again, acute miliary tuberculosis—tubercular phthisis—is by no means an infrequent sequel of a catarrhal pneumonia.

You are already familiar with the clinical portraits of both forms of pneumonia, and I pass at once to the

consideration of some of the more prominent differences between the pneumonias of early and later life.

1. As to the portion of lung involved in the disease. In the adult a croupous pneumonia is very generally limited to the lower lobe of the right lung, but in children it attacks indifferently either lung or any lobe. In a fair proportion of cases the upper and middle lobes are affected with or without implication of the base. Nurslings or feeble children of any age are especially apt to suffer from an apex pneumonia, but it is by no means uncommon in the robust, as in the case before us this afternoon. In fifty-one cases recorded by Meigs and Pepper, the upper lobe was affected in twenty, while in thirty-one the base of the lung was the seat of the disease.

In the catarrhal form of the disease, which is generally bilateral, there also exists in children a greater proneness to implication of the upper lobes than in adults. It is, therefore, an invaluable practical rule, if you would avoid falling into error, to carefully interrogate the apex as well as the base of the chest when a child is ill with a suspected lung trouble of any kind.

A pneumonia limited to the upper lobe would in the adult be open to the gravest suspicion; indeed, it would very positively indicate the presence of a tubercular deposit or a specially vulnerable constitution. In the young, however, it is not unusual to find the apex involved, without any suggestion in the family record or previous history of a tubercular diathesis, and occasionally the inflammation will run its course without anything phenomenal in the symptoms or termination. But it is important for you to remember the clinical fact that, as a rule, an apex pneumonia, be it lobar or lobular, does not run the typical course with which you are so familiar. The inflammatory product is more slowly deposited and more slowly removed, the febrile movement and nervous symptoms are out of proportion to the amount of lung involved, and the whole attack wears a graver physiogomy. This fact will occasionally render your diagnosis very doubtful. Physical signs can only tell the presence, not the nature, of the consolidation. I am satisfied that in many cases it will be impossible to decide until sufficient time has elapsed whether a given solidification of the apex is due to acute tuberculosis or to a slowly resolving pneumonia. Usually, however, the history of the attack, the child's inheritance, the condition of the lymphatic glands, the extent of the solidification, and the thermometric range will guide us to the truth. Ziemssen was the first to point out that in a lobar pneumonia, even of the apex, the thermometer registers a higher degree, and shows less fluctuation between morning and evening temperatures than in consolidation from tubercular deposit.

The difficulties are greater when the differentiation must be made in the lobular disease. Dr. Buchanan makes the statement in his Lettsomian Lectures that, "For anything that can be made out by the stethoscope, the thermometer, or the most careful clinical inquiry, it is absolutely impossible to say whether the lung signs are due to acute tuberculization or to lobular pneumonia."

2. As to the import and frequency of some of the symptoms. The chill which so frequently ushers in a pneumonia in the adult is rarely met with in the child, and if present only amounts to a sensation of chilliness. The nervous symptoms are much more pronounced in the child than in the adult. Very often a pneumonia, especially of the lobar form, is announced by a convulsion, and these cases are not necessarily marked by other cerebral disturbances, or do not always foretell the graver forms. The excitable nervous organizations of children render them peculiarly liable to these "nerve storms." In many cases, either with or without the initial convulsion, the nervous symptoms assume such prominence as to distract attention from the real seat of disease. Headache, vomiting, delirium, stupor, and convulsions, constitute a grouping of symptoms which will easily mislead a careless practitioner. It is important to bear in mind that cerebral symptoms are apt to predominate when the upper lobe is involved. While the rule is not absolute, an apex pneumonia rarely runs its course without the presence of more or less decided brain symptoms, and, for this reason, many authors designate this form as cerebral pneumonia. This peculiarity is well exemplified in the case before us—the initial convulsion, the stupor, the boring of the occiput into the pillow, and the muscular twitching are quite characteristic. A knowledge of the manner in which a pneumonia may simulate a meningitis will be enough to put you upon your guard. Occasionally you will be compelled to withhold, for a time, your diagnosis, but usually a careful exploration of the chest will lead to a correct interpretation of the symptoms.

The sputum does not possess the same diagnostic characters in the child as in the adult. Under five or six years of age, children rarely expectorate. Unless taught by the hard experience of a whooping-cough or chronic bronchitis, the sputum is coughed into the fauces and swallowed. When present it is not rusty and viscid, even in lobar pneumonia, but is light in color, thin, frothy, and less tenacious. In the catarrhal form, as, you know, the extruded matter is not an exudation from the blood, but is the product of cell proliferation commingled with the secretion of the mucous glands. Exudation of red blood-corpuscles rarely occurs in catarrhal inflammations, and as these form so large a proportion of infantile pneumonias, the absence of rusty sputa is easily explained.

Children with relatively the same extent of lung involved ordinarily suffer greater dyspnœa than adults. This is seen in the rapid breathing, the action of the auxiliary respiratory muscles, and the infra-mammary retraction of the thoracic walls, which attend upon comparatively mild grades of the disease. In a case of moderate severity the breathing rises as high as forty or fifty respirations per minute, while in the graver forms they may number eighty or ninety, and the pulse-respiration ratio will be correspondingly altered. Not infrequently, the rhythm of the respiratory acts is so changed that the pause comes after the inspiration instead of after the expiration.

There are three symptoms which possess much greater diagnostic value in the child than in the adult—the respiratory moan, the flapping of the nares, and the sulcus around the base of the chest. The latter tells unmistakably of the impeded entrance to air, and is usually indicative of capillary bronchitis, lobular pneumonia, or laryngeal stenosis. Although the expiratory moan is not, as it was formerly considered, pathognomonic of intra-thoracic disease, it does indicate, with tolerable correctness, a pleurisy or lobar pneumonia.

Another striking peculiarity of infantile pneumonias is the insidious manner in which they are frequently developed. We have already spoken of the closeness with which lobar pneumonia may simulate simple meningitis, and might with equal propriety draw attention to the similarity which often exists between chronic lobular pneumonia and tubercular meningitis. As thorough a clinician as Juergensen states that it is often impossible to determine with certainty whether a child suffering from catarrhal pneumonia has not at the same time a moderate crop of tubercles in the brain.

A sub-acute pneumonia not infrequently creeps on during the progress of an acute illness, especially an entero-colitis, and presents but few symptoms to indicate the dangerous complication.

Badly nourished, especially bottle-fed, babies will, without any acute disease, frequently suffer from passive congestion of the lungs or lobular collapse; due to the feebleness of the respiratory and circulatory movements, which will result in a form of catarrhal inflammation—hypostatic pneumonia—and yet be announced by very indefinite pulmonary symptoms.

An important therapeutic hint may be drawn from these facts. When a feeble or young infant is seriously ill with any acute disease, it is of great advantage to insist upon frequent changes of position, and even allowing it, at intervals, to rest upon its abdomen so as to obviate this tendency to hypostatic congestion.

3. As to physical signs.

Pneumonia in the child is recognized by the same physical signs as in the adult, and yet there are some important modifications, which, if ignored, will inevitably lead to mistaken diagnoses. It may, perhaps, be unnecessary to refresh your memories as to the peculiarities of the normal breathing of young children.

You know that in the forced breathing of infants, or in the ordinary respiration of those over two years of age, the normal vesicular murmur has a blowing or bronchial character, to which the name of "puerile" was given by Laennec. Therefore, breathing sounds, which are normal in the infant, would in the adult signify morbid changes in the parenchyma of the lung.

Percussion in the child normally elicits a more sonorous sound than in the adult, on account of the thinness of the chest walls, the smaller bulk of the lungs, and the ease with which the air in the primary bronchi and trachea is thrown into vibration.

Another point of undoubted clinical importance is that there is often a normal difference in the resonance of the apices of the child's chest, the opposite of that found in the adult. Dr. Buchanan has shown that, in healthy children under seven years of age, the left apex is quite commonly a little duller than the right.

Beyond doubt many practitioners are constantly misled by failing to appreciate the extent to which tension of the abdominal muscles may modify the results of physical exploration of the chest. The moment you attempt to percuss a child, it, voluntarily or involuntarily, employs what Vogel terms "abdominal pressure," whereby the abdominal viscera are forced upwards and encroach upon the thoracic cavity: on this account the line of dulness is different on opposite sides and is constantly changing on the same side of the thorax.

The liver, which is relatively very large in the child, may in this way cause dulness up to the spine of the scapula. To eliminate error from this source, it is essential that you continue your examination in one spot long enough to percuss at the moment of the deepest inspiration and the most complete expiration.

The crepitant râle—that fine, sharp crepitation which is almost pathognomonic of pneumonia in the adult, is rarely heard in children under three or five years of age; and when heard, it is a louder, coarser, moister râle, resembling in character crepitation redux or a fine subcrepitant râle.

Vocal fremitus, which has such diagnostic value in the adult, is less trustworthy in the child. Very often it is absent from both sides of the chest, and sometimes seems to be more marked upon the sound than upon the diseased side. When it is found *only* on the *diseased side* it, of course, becomes a valuable indication of solidified lung. The physical signs of consolidation are, as a rule, however, sufficiently marked in a croupous pneumonia affecting the youngest child to enable you with proper care to reach a correct diagnosis. But in the catarrhal form the physical signs are less distinct, excepting as they reveal the ever-present bronchitis, and upon them *alone* it would often be impossible to build up a diagnosis. The nature of lobular pneumonia offers a ready explanation of this fact. In the common form of the disease, the lung is studded with pneumonic patches, varying in size from a pea to a filbert, each consisting of one or more lobules separated from each other by a network of healthy crepitating lung tissue. If, as often happens, several contiguous lobules are involved so as to cause consolidation of a considerable area, the physical signs are very pronounced and unmistakable. Physical exploration alone, will only in exceptional cases enable you to decide, whether the solidification in a given case is due to simple collapse of lobules in the course of a capillary bronchitis or to pneumonic patches. The exceptional cases are when the signs fluctuate under examination or within short periods: for instance, dulness, and bronchial respiration, which would disappear after severe coughing, would positively indicate collapse. The diagnosis of a lobular pneumonia must therefore be largely made from the history and symptoms, reinforced or not by the physical evidences of consolidation.

If in the course of a simple bronchitis, the fever is suddenly increased, the cough becomes hacking and painful, the breathing more labored and the pulse-respiration ratio altered, the accession of a catarrhal pneumonia is very certain, and if now, in addition to the ordinary bronchial râles, you can detect localized dulness, tubular breathing, and other signs of solidification the chain of evidence is complete.

Catarrhal pneumonia is usually a bilateral disease, and a characteristic form for the solidified portion to take is that of a pyramidal strip extending two or three inches along each side of the spine, resembling in these respects simple lobular collapse. The thermometer renders invaluable aid in differentiating between capillary bronchitis and its sequelæ, catarrhal pneumonia and lobular collapse.

Capillary bronchitis is normally attended with only moderate febrile movement, the mercury fluctuating between 102° and 103° F. A sudden exacerbation of fever in the course of a bronchial catarrh, in which the thermometer registers 104° F. or higher, strongly suggests the onset of a pneumonia, while a sudden and marked fall of the mercury without a corresponding improvement in the other symptoms points to lobular collapse.

There are other peculiarities to which attention might be called, but we have probably said enough to convince you that infantile pneumonias are worthy of your earnest and conscientious study.

ORIGINAL ARTICLES.

THE INFLUENCE OF DOSE ON THE PHYSIOLOGICAL AND THERAPEUTICAL ACTION OF REMEDIES.

By ROBERTS BARTHOLOW, M.D., LL.D., Etc.,
Professor of Materia Medica and Therapeutics in Jefferson Medical College, Philadelphia.

In the study of physiological therapeutics, hitherto, not sufficient attention has been given to the subject of dose as a factor in the results. It is true, we find references here and there to the differences of action thus produced, but it is not given the fundamental importance properly belonging to it. With a view to my own instruction, I have, during the past year, been making some experimental studies in this direction. I attempted, more especially, to ascertain if there are any general formulæ, by the aid of which we can more successfully interpret the influence of quantity over qualitative actions. The

conclusions at which I arrived I put in the form of postulates, and the experimental and clinical evidence will follow.

Medicines acting on a part, a tissue, or an organ, can only increase or diminish the normal function, and cannot give to the function a new direction. For example, atropia increases the action of the heart and digitalis slows it, but neither can make the heart perform any other duty than its own.

The irritability—that is, the power to react to impressions—of a tissue or an organ, may be increased, or diminished, or destroyed, by medicines affecting function. Those medicines which increase irritability, must, if their effects continue, ultimately cause the same results as those lessening irritability from the beginning of their action—for it is a law that, if excitation of a function continue, the irritability of that function will ultimately become exhausted and its action cease. For example, strychnia increases the irritability of the reflex function, but if its effects continue, the reflex function after a time is exhausted and ceases.

I cannot too strongly insist on the importance of these propositions. The first one is simply an axiom. There is no remedy that creates new functions; not one that does more than increase, or lessen, or destroy function. There are remedies which cause morbid states; but these derange function—briefly, it may be, heighten the activity of particular organs, and ultimately destroy the power to functionate; yet they do not force the organs into new modes of activity. A careful survey of the whole field of remedies will only bring confirmation to this proposition, and I therefore pass on to the next.

The property of *irritability*—which I have defined to be the power to react to impressions—is possessed by all organs. When a motor nerve is irritated, the muscles to which it is distributed contract; when a sensory nerve is irritated, pain is caused; when a gland is irritated, its secretion is increased. It is no less true that persistent irritation, or stimulation, ultimately destroys the power to functionate—in other words, arrests function. The proofs of this are unanswerable. If a motor nerve is long irritated, the muscle first contracts, then tetanizes, and finally the nerve ceases to convey any impression, and the muscle relaxes or is paralyzed. If a sensory nerve is subjected to permanent irritation, pain is first produced, then numbness, and finally analgesia and anæsthesia result. If a gland is persistently stimulated, at first the normal secretion is increased in amount, then a pathological secretion is produced, and, finally, the gland strikes work entirely. The whole matter is resolved into the physical law—"*To every action there is an equal and opposite reaction.*"

The action of strychnia, which I have given as an example, is a striking illustration. If $\frac{1}{200}$th grain of strychnia be injected into a frog, the most characteristic tetanizing action follows. So acutely exalted is the reflex function, that the merest jar of the table will cause a general convulsion, the body being strongly rigid. Now, if into a frog of the same size, three grains of strychnia be injected, there may be no convulsions, or very transient slight spasms, but the whole body will be completely relaxed, and no irritation will cause muscular action. The explanation is obvious. Persistent irritation of the reflex and motor apparatus finally exhausts its irritability. A mere scratch, or a blow with the hammer, will destroy the magnetic property of a permanent magnet. There are remedies such as curara, conium, and the bromides, that do not stimulate, but depress the spinal functions from the onset of their action. It follows, then, that those remedies which first stimulate, and afterwards depress, act in the same way, if their effects continue, as do those remedies which depress from the outset.

Such different, and even opposing, action of the same remedy may result from dose. We have seen that in strychnia; it is true of many other remedies as well. We can only understand how such differences of action may occur by the light of the general principles which I have enunciated. Let me now offer some examples:

Quinia, one of the most important remedies, exhibits marked qualitative differences when administered in small and large doses. Does quinia increase or lessen the intracranial blood-supply? is a question which has been much discussed. Those who have given it in small doses—say from two to five grains every four hours—have seen the pulse increased in force and frequency, the conjunctivæ injected and retinal vessels full, and the activity of the functions, generally, raised above the usual level. They hold, therefore, that quinia increases the intracranial circulation. Experimental evidence has been adduced in support of the clinical. The cerebral meninges of animals exposed, the membranes are seen, under the action of quinia, to become more vascular, and the cephalehæmadynometer registers higher intracranial blood-pressure. The very opposite conditions are observed when large doses are administered—say a drachm or more. Then the pulse is slowed, the face grows pale, the retinal vessels become small, and there is much of that tinnitus and vertigo significant of cerebral anæmia. The experimental evidence is in harmony with the clinical: the cerebral meninges are pale, exsanguine, and the blood-pressure is low. Still more conclusive is that accidental experiment made on man: the quinia amaurosis—in which there is an extreme pallor of the optic disks, the vessels of the largest size appearing as minute threads, and large numbers of vessels usually in view have disappeared. Several examples of this kind have been observed by Knapp, and other ophthalmologists, after the exhibition of large doses of quinia.

The antipyretic effect of quinia is now universally admitted, but a strange misconception exists in the minds of some as to the quantity required. That the normal temperature is depressed by quinia, is true only of enormous doses and to a slight extent, but the rise of body-heat produced by active exercise and by the febrile process, is prevented by scruple to drachm doses, but not less will succeed. To give small doses at short, regular intervals, to stimulate the organic functions, and large doses to lessen their activity, is a strictly logical process. The mechanism is not difficult to comprehend,

aided by the formula I have given. We need not fall back on that convenient, but entirely hypothetical and supposititious heat-centre. There is chemical activity enough, surely, to account for heat-production; and for its regulation within normal limits the provision is complete. In the slowing of the blood-current, and diminished amount of blood distributed; in the lessened activity of the red blood-globules, and the consequent depression of the chemical actions and interchanges produced by large doses of quinia, we have a sufficient explanation of its influence over the heat-function.

Another striking example of the influence of quantity over qualitative actions is afforded us in *alcohol*. The difference in the action of small and large quantities, is the explanation of the alcohol paradox, in regard to which there has been almost endless discussion. That alcohol in moderate quantity stimulates the circulation and increases the activity of the organic functions, are facts now universally held. That alcohol in large quantity slows the heart, lowers the body-heat, and depresses the organic functions, are also facts demonstrated clinically and proved by experiment. Are these facts reconcilable? Alcohol may increase the action of the heart in two modes: by a reflex impression having its origin in an excitation of the nerve-endings in the stomach; or by its own oxidation or combustion in the organism, yielding up force which is utilized by the cardiac motor apparatus, or both modes of action may be concerned in the result. When large quantities are ingested, the stage of stimulation is brief, and is followed by depression, which is seen in the lessened cardiac action, in the lowered temperature, and in the suspension of the cerebral functions. The amount of alcohol is in excess of the oxidizing power of the organism, and the evolution of force, especially of nervous energy, is checked. Indeed, no medicinal agent more perfectly illustrates the physical law—to every action there is an equal reaction. From the therapeutical side, there is no fact of greater importance. Not long since I saw, in consultation, a case of diphtheria in an adult, in which the physician, a very competent man indeed, was trying to raise the pulse up from its low state. He poured in great doses of brandy, and was in despair that the pulse would not rise above 56, and the temperature would not attain a higher point than 98° Fah., the functions generally appearing torpid. I suggested that he substitute a moderate quantity of champagne for the large doses of spirit, and in a few hours a striking change was observed. Who does not recall within the range of his own experience similar examples? This very practical point is a tempting topic for further discussion, but I must pass on to other illustrations of the great law of dose. I will next examine the influence of quantity on the qualitative results of the administration of *opium*.

We often hear the statement that opium is more stimulant, and morphia more sedative. Although there is a small measure of truth in this formula, the difference lies rather in quantity. Opium may, I think, be justly regarded as the most powerful and sustained stimulant that we possess; at the same time it is the most efficient remedy against the first stage of the inflammatory process. The stimulating effect of opium is well exhibited in its antagonizing action of those remedies which cause death by failure of the heart, notably atropia, aconite, veratrum viride, etc., and in its preventing failure of the weak, dilated, or fatty heart. To obtain the stimulating effect of opium, all the world knows that it must be given in small and repeated doses. Of course, when the impressionability of the system has been reduced by the opium habit, the merely stimulating dose corresponds. Large doses slow the heart, raise the peripheral tension, and thus lessen the blood-supply to organs and tissues. These effects can be admirably shown by the sphygmograph, when properly adjusted. If a normal tracing is first taken, and then morphia injected subcutaneously, the instrument kept in position, obviously, the conditions being the same, the change in the tracing must represent the action of the drug. Tracings taken in this way exhibit very striking changes,[1] indicating the effect of morphia on the rate of pulsation, and on the tension of the vessel. There has been an enormous clinical experience, also, proving the power of opium in full doses to check inflammation by diminishing the blood-supply to the inflamed tissues. This mode of treatment has been carried to its utmost limits by Dr. Alonzo Clarke in the treatment of peritonitis—carried to the point of narcotism, with a reduction of the pulse to 40 per minute. There are two practical points which I should not fail to mention in connection with this treatment: 1. The utility of opium as a remedy for inflammation, is limited to the stage of congestion, and ceases when stasis and exudations occur. 2. Those large doses by which so decided a reduction in the pulse-rate is effected, will finally exhaust the organs which were at first stimulated. We should not here, as everywhere, fail to realize that fundamental physical maxim—to every action there is an equal and opposite reaction. No point in the whole circle of the effects of opium better illustrates this principle than the action on the intestinal tube. Opium in small doses stimulates the splanchnic—the inhibiting nerve for the intestine, as the pneumogastric is for the heart—and in large doses paralyzes it; hence it follows that in small doses opium constipates, and in large doses tends to relax. See how admirably the results of the physiological study illuminate and confirm empirical observations!

Digitalis affords us another capital illustration of these principles, and, from the practical point of view, their application has an importance that can hardly be overestimated. To confine my observations to the narrowest limits, I will only refer to the effects of digitalis on the heart, and its associated nervous apparatus. The ancient notion of the power of digitalis as a heart poison, has been quite supplanted by the modern notion of its power as a heart tonic. There was an element of truth in the ancient, as there is a mischievous fallacy in the modern, notion. Whilst the ancient theory limited the therapeutical applications of digitalis; in the

[1] Treatment of Diseases by the Hypodermatic Method; 4th edition, Philadelphia, 1882.

modern conception of its powers, the danger attending its action is too little regarded. Indeed, from the loose talk about digitalis, one would suppose it to be a heart tonic without limitations. Almost more completely than any other remedy it illustrates the difference between large and small doses; that whilst the former stimulate, the latter exhaust. In moderate medicinal doses it stimulates the pneumogastric and its terminal inhibiting ganglia, and the vaso-motor system. If the stimulation continue too long, or if the dose be too large, the irritability of these organs is exhausted; in other words, it paralyzes the organs which it first excited. When digitalis is given in a quantity to slow the heart decidedly, if the patient assume the erect posture, an extremely rapid and weak action is substituted. A most striking example, as showing the nature of its powers, is the fatal case of digitalis poisoning reported by Boehm. A girl died on the fifth day from paralysis of the heart, after taking a single large dose. The old idea of an accumulation of power and its sudden liberation in an energy that stops the heart, simply means the paralysis which follows overstimulation. In this sense, we may well be on our guard against the "cumulative effects" of digitalis. The practical conclusions to be deduced from these facts are of immense moment: (1) in the administration of digitalis as a cardiac tonic, the dose to be given is the minimum quantity necessary to produce the effect, and (2) this dose must not be continued so long as to endanger the working power of the motor apparatus. Here, I might, if the topic were not foreign to the purpose of this paper, indicate how the principle of antagonism is utilized in the conjoint administration of remedies that oppose the tendency to cardiac depression without interfering with the curative action.

Pilocarpine, one of the recent and valuable contributions to our materia medica, illustrates in a most interesting manner the influence of dose. The first effect of this remedy is to excite: the heart quickens its movements, the face becomes flushed, and the cutaneous vessels are so filled that the surface grows warm; then the excitement of the salivary and sudoriparous glands occurs, and a profuse secretion is poured out. Just in proportion to the excitement is the after-depression, in which the temperature falls, the heart languishes, and the organic functions in general become feeble. It is now well known that any dose above that necessary merely to cause the desired activity in the salivary and sudoriparous glands, may produce a dangerous, even a fatal, depression. In the action of this remedy, the physical law has a most exact exemplification—for to the action there is an equal and opposite reaction.

I might thus continue multiplying examples of the influence of quantity over qualitative actions, all drawn from the organic materia medica, and from the group of agents affecting the nervous system, chiefly. It is desirable, however, to seek further illustrations of the same truths from the mineral kingdom, and from remedies having different actions than those involving the nervous system. The group called *tonic* will afford us some excellent examples. There is no remedy more used, also more abused, than iron. There are but two ultimate purposes subserved by its use: 1, to stimulate the primary assimilation; 2, to promote constructive metamorphosis, or the metabolism of tissue formation. The purpose should determine the dose, and the quantity given will determine the character of the result. When iron is used to stimulate the function of digestion, as a large surface is to be acted on, large doses must be administered. It is perfectly obvious that if the digestive apparatus be continually goaded to increased effort for too great a length of time, a disastrous depression must presently follow. In this fact we have an illustration of the old rule, to suspend occasionally the administration of iron when a long course is carried on, and give a purgative. When the purpose in view is to correct anæmia, to promote constructive metamorphosis, and to energize the organic functions generally, again the dose is determined by the object. Is a recent and powerful but temporary depression to be overcome? the dose must be adequate. Does a more lasting condition of depression in the function of constructive metamorphosis exist, the dose must be one which can be administered for a sufficient length of time without causing an opposing reaction.

Not in a less degree are these principles applicable to the administration of "bitters," and other vegetable tonics. How often do we observe full doses of these remedies administered without maintaining the good effect at first obtained! The first genial excitation of the digestive apparatus ceases under a persistent repetition of the impression. Large doses for a temporary purpose, small doses for lengthened use, should be the formula for our guidance, with the limitation always kept in mind that too persistent and prolonged stimulation of any organ must result in after-debility.

When we extend our inquiry into the class of remedies whose office it is to cause some kind of an evacuation from the body, we discover some interesting facts regarding the influence of quantity. Evacuants have a dual action. There is a preliminary impression on the organ centre or apparatus —it may be sedative; it may be irritative—and is followed by the action of expulsion and increased excretion. By a small or minute dose we obtain the former; by a large dose, we procure the latter. *Calomel* and *ipecacuanha* are good representatives of the class inducing this double action. It is a fact of daily observation that such small doses of calomel as the $\frac{1}{20}$ gr. to $\frac{1}{6}$ of a grain exert a remarkable sedative effect on the stomach and upper intestine. For example, vomiting may be thus arrested when other means fail. For my part, I am unable to subscribe to the doctrine that one grain of the centesimal dilution, or $\frac{1}{100}$ of a grain of calomel, will have any obvious effect, unless given excessively often, say every ten or fifteen minutes. I place the minimum at $\frac{1}{20}$ of a grain, with the expression of my conviction that there is little utility in going below $\frac{1}{12}$ of a grain. Whilst in cases of duodenal catarrh and catarrhal jaundice, considerable doses of calomel irritate not only the mucous membrane,

but the hepatic cells, small doses have an undeniable good effect in allaying irritation.

Apropos of the action on the liver, permit me to digress so far as to say that the liver serves to excrete various mineral poisons, which hence tend to accumulate in the hepatic cells, to irritate them, and to impair their functions. The salts of mercury, silver, gold, etc., may be mentioned. These remedies in minute quantity, stimulating by their presence to the slightest extent, promote the activity, the nutrition, and the functional power of the organ. Frerichs mentions the discovery by him of a gall-stone having for its nucleus a globule of mercury.

Turning now to *ipecacuanha*, we find that this has in small doses a sedative effect—a stimulating or irritant action in large doses. Small doses will sometimes arrest vomiting of nervous or reflex origin. The homœopathists have made much of this, and claim that to admit it is to admit the truth of their ridiculous dogma of similars. The facts are so susceptible of a truly scientific explanation, that there is no need to have any humbug mysticism over them. The so-called *tolerance*, produced by the repeated use of large doses, means the diminution of irritability, the inevitable result of over or continued stimulation.

Calomel and ipecacuanha are not the only evacuants having the dual action to which I have alluded; all possess these properties to a greater or less extent. *Colocynth* is an excellent illustration of the same truth. Whilst calomel in small quantity allays irritation of the upper digestive tube, colocynth in minute doses is sedative to the lower—to the ilium especially. As calomel in the minimum dose will allay vomiting when other remedies fail, so colocynth tincture, in a small dose, will stop intestinal pain and irritation when other remedies are unsuccessful.

Finally, the action of diuretics illustrates the influence of dose on physiological and therapeutical action. Any remedy may serve to point the moral, but, for several reasons, cantharides is to be preferred. The stimulating, irritating quality of cantharides in full medicinal doses everybody knows, but in minute quantity it has distinct sedative effects on the urinary apparatus not so well known. The evidence is clinical. In some cases of irritable bladder, for example, it has a remarkably quieting effect when exhibited in small doses. In chronic catarrh of the genito-urinary tract, the same effect is produced by the same mode of administration.

Thus throughout the whole field of pharmacology, we find that qualitative results are largely influenced and determined by the quantity administered. In fact, so certainly true is this relation, that in the statement of physiological actions and therapeutical results, the quantity of the remedy administered is an essential element, without reference to which exactness is unattainable.

A CASE OF CHRONIC OTORRHŒA FOLLOWING SCARLATINA.

MASTOID DISEASE; CARIES OF THE BODY OF THE THIRD CERVICAL VERTEBRA; RETRO-PHARYNGEAL ABSCESS; RECOVERY.

(*Read before the Union Medical Society of Northern Michigan, May 21, 1882.*)

BY F. GUNDRUM, M.D.,
OF IONIA, MICH.

On February 28, I was called to see Miss W.; age twenty-five; native born.

History. — Parents of this patient are strong, healthy English people. The patient possessed good health until eight years ago, being large and strong for her age. Eight years ago she contracted scarlatina, of which she was very ill. She finally recovered from the acute attack, but with shattered health and a discharge from both ears. This ceased in the left ear about eighteen months ago, but has continued in the right up to the present. Hearing has become very indistinct in both ears, so much so that without artificial aid she is scarcely able to hear the loudest conversation. Since about a year and a half ago, a pain has developed in the right auditory meatus and region of the mastoid, laterally extending into the base of the skull and cervical region. This has gradually increased in severity, until at times it is excruciating. A jar, while walking or riding, for the last two or three months, has produced such severe pain in the base of the cranium and upper cervical region that riding in a vehicle has been entirely abandoned, while walking is performed with extreme caution. The movements of the head have gradually become less on account of the pain produced, and recently it has become fixed. For several months past she has had a constant profuse discharge from the pharynx of a tenacious mucus, which she hawks up every few moments. Deglutition has become painful. The discharge from the right ear has become very offensive and dark in color. Her general health has grown from bad to worse. She has gradually wasted away, and, although not tested by the scales, she thinks she has lost one-fourth of her weight. Her speech has become muffled, indistinct, and attended with pain.

She has received treatment for years, both local and general, but without any material benefit.

Present Condition.—The patient is a tall brunette; very intelligent. She has an ample osseous frame; all adipose tissue gone.

It is noticed, while the patient is walking around in the room, that she does so very carefully, avoiding all jars, and bending the head neither to the right nor left. Whatever the patient does, she scrupulously avoids jarring the body or moving the head. She can not be induced to "come down on her heels" with any force. The right ear, as noted above, has coming from it a dark, offensive purulent discharge. The tympani of both ears are gone, together with the ossicles. In the left ear cicatrization has taken place; in the right there are numerous granulations in the cavity of the tympanum. The right mastoid process seems to be slightly swollen, which seems to be due to a slightly congested con-

dition of the overlying soft parts. Firm pressure gives slight pain, but percussion elicits nothing abnormal. In the neck, on the right side, commencing about three-quarters of an inch below the mastoid, and continuing down the neck for four inches or more, being most distinct just in front of the sterno-cleido-mastoid muscle, there is a marked diffuse swelling. The overlying skin is normal in color and, seemingly, in temperature. It is painless upon deep pressure. It is boggy, but fluctuation could not be made out with certainty. The muscles controlling the movements of the head are abnormally rigid, which is increased when any attempt is made to move the head. None of the cervical vertebræ show any undue prominence, but pressure of the spinous process of the third and fourth produces severe pain in the right side of the neck and right base of skull.

Pressure on top of the head, directed perpendicularly, gives severe pain, while any manœuvre to rotate it is resisted. When the head is raised by placing one hand under the chin and the other under the occiput immediate relief is obtained, and then slight movements of the head can be made without the least pain. The posterior pharyngeal wall is covered with a tenacious mucus, and seems to be pushed forward, lying against the relaxed soft palate. This forward displacement struck me with great force (it is the first case I ever saw), and aroused my suspicions at once. Having patient open her mouth as wide as possible, I passed my finger against the posterior pharyngeal wall, when I got distinct fluctuation—it was deep, but distinct. To confirm my conviction, I passed an aspirating needle and obtained nearly four ounces of thick, tenacious pus. The pharynx assumed a normal shape, the wall receding to its former position. To our great surprise, when we had finished the aspiration, it was noticed that the swelling in the neck had all subsided. The aspiration afforded our patient great relief. Her speech became nearly natural and painless. Deglutition was performed with ease and comfort. The patient's general condition is bad in the extreme. She looks sallow, emaciated, and careworn. She has no appetite, and if she ever feels like eating anything, the pain deglutition produces almost gives her the horrors. She sweats at night. Sleep is almost unknown, from the pain in the neck and the constant accumulation of mucus in the throat. The temperature is 102°, and the pulse 116.

The patient was ordered syrup of hypophosphites of quinia, iron, lime and strychnia, cod-liver oil, old stock ale, daily bathing, and as much air and sunshine as the weather would permit.

March 9.—The patient has improved but slightly. She could not retain the cod-liver oil in any form. The temperature has ranged between 100° and 103°; pulse 100 to 120. The post-pharyngeal abscess has refilled. The soft tissues over the right mastoid process seem to be more swollen than at my last visit. Mastoid disease had been strongly suspected by the lady's brother, Dr. C. W. Wooldridge, and having good reasons to share his supicions, I determined to open the mastoid and see. Accordingly, assisted by Dr. S. V. Romig (who gave the anæsthetic and assisted), I made the usual incision through the soft structures, and by aid of Sayres' periosteal knife, raised, after dividing it, some of the periosteum. After laying bare a portion of the process, I discovered a small opening in it. Unmistakable evidences of ulceration were present. This opening was enlarged, the bony tissue being very friable and breaking down easily, until a free opening was made. The process bled freely. No loose bone could be detected. The mastoid showed unmistakable evidence of a protracted inflammation and ulceration. Quite a quantity of the brittle, inflamed cancellous structure was removed—scraped out—considering it better out than in.

With a hope, if possible, of finding a communication between the mastoid and abscess in the neck, I made every attempt with probe and warm carbolized water and syringe to find it, but in vain. After hemorrhage had ceased, the mastoid was thoroughly cleansed with a five per cent. solution of carbolic acid, a drainage tube inserted, and the wound closed. A two and a half per cent. solution was prepared to be used once in two hours through drain-tube. Morphia in sufficient doses was ordered. The patient rallied well from the operation.

24th.—The patient has entirely recovered from the operation, and is up and around. Her general health seems to be slightly improved. The pulse and temperature are about the same; pain in the mastoid gone, but as much pain as ever in the cervical region. There is a sweet, purulent discharge from the drain-tube. The post-pharyngeal abscess having filled up again, it was aspirated with same results as before. The swelling in the neck, which had reappeared, disappeared again; the drain-tube was removed and left out; a solution of carbolic acid and chloride of zinc was prepared, and mastoid to be washed out with it. The following pill was ordered:

℞. Iron by hydrogen,	ʒj.
Quin. sulph.	gr. xlviij.
Ex nux vomic.	gr. vj.
Hypophosphite of lime,	ʒj.

M.—Make into 24 pills; 1 three times a day, after meals.

I had made up my mind that there was disease of the third or fourth cervical vertebra; which one I could not positively say, as pressure on both their spines produced pain, but more especially on the third; and as no projection had as yet taken place, to prevent a deformity was the great desideratum. I operated on mastoid before applying a jacket, so that patient would not be compelled to keep the bed with a jacket and jury-mast; so as soon as the patient got in tolerable shape, eleven days after the operation, I put on the jacket.

On the 20th of March, assisted by Dr. Wooldridge, I applied a plaster-of-Paris jacket and jury-mast. I wanted to save the father the expense of a skin-fitting shirt, and told him to buy an all-wool undershirt from a dry goods store, and have the mother fit it accurately. After reaching the house, nine miles in the country, it was found that the shirt

fitted "like a nigger's shirt on a bean-pole" (Sayre). It had to be made over, and by the time we got the shirt fitted, our poor patient was tired out. I advise all who ever expect to put on a plaster jacket to have a skin-fitting shirt made to order. It is the first time that I ever tried this economic plan; it shall be the last. After fitting the patient as well as possible, I found her so emaciated that it became necessary not only to pad around bony prominences, but to envelop the whole trunk in a layer of cotton, This was the most emaciated subject on whom I ever saw a jacket applied. Having only one assistant, the time occupied was somewhat longer than usual, during which time our patient became very faint. Had she not been an iron-willed girl, our efforts must have been a failure. After the jacket had set, and the patient had rested, her head was suspended, which relieved all pain in the neck. A complication soon came on which I never saw before. The articulations in the lower maxilla became very sore, and the jaw became almost stiff; no solid food of any kind could be taken; mastication was entirely suspended, although the pressure was varied from time to time. (The patient, since the application of the plaster, was almost under the entire care of her brother; I was consulted occasionally.) The father's ingenuity came to her relief. He took a small piece of iron, fastened it to the jury-mast, where it passed horizontally over the head, so as to project beyond the face several inches; to this he fastened a strap, and the other end to chin-piece. This remedied the difficulty entirely. Since the application of the jacket the patient has steadily improved; she has nearly regained her former weight and strength. The mastoid has closed up; the ear ceased to discharge; the post-pharyngeal abscess has not refilled. All pain in neck and mastoid process has disappeared, and Dr. Wooldridge, as well as myself, consider the patient entirely cured.

P. S.—She wears the jacket only during the day, having made it into a corset, more for a protection than anything else.

LITHOLAPAXY IN A WOMAN.

By EDWARD T. CASWELL, M.D.,
SURGEON TO THE RHODE ISLAND HOSPITAL, PROVIDENCE, R. I.

Since the introduction of Dr. Bigelow's brilliant procedure for the removal of stone in the bladder, allusion has been made by several writers to its adaptability to women. As I have seen no notice of any case in which the operation has been performed upon the female, I venture to report one. The procedure presents great advantages over the methods previously in use, which may be summed up as removal of the entire stone through the dilated urethra, or by cystotomy. By the first of these methods a greater or less degree of incontinence is likely to ensue, and the second involves the closing of the wound in the bladder, with the possible risks of a vesico-vaginal fistula. In comparison with either of these, the operation of lithotapaxy is far preferable. The facility of execution, and the entire freedom from after-effects, are sufficient to commend it at once to the surgeon.

This case was the ninth of my series, the rest of course being in males, and the difference between the operation in the two sexes was much greater than I had imagined. The following is the record:

Mrs. L., aged 51, English, has been in this country but six months. Nine years ago she passed the first stone, and several at different times since, all of them small. The last was passed in January, 1880. She has suffered from the present stone for four months, and complains of pain, frequent micturition, with blood and thick mucous discharge in the urine. The pain, while in my office at a preliminary visit, seemed excruciating. The stone was of course easily felt both by the sound in the bladder and by the finger in the vagina. . Having etherized her, I dilated the urethra by the passage of conical steel sounds up to 29 Fr. A modified Thompson's fenestrated lithotrite, and one after a model of Dr. Keyes, were both used. The fragments were evacuated through a straight tube, 28 Fr., which passed with the utmost ease. The only drop of blood visible in the operation was at the meatus after the introduction of the No. 29 tube in dilatation. The fragments weighed when dried 100 grains, and the character of the stone was phosphatic. Four days after the operation, Dr. Kemp, of Lonsdale, whose patient she was, wrote: "She has not had an unfavorable symptom, and would be up and about her work but for a slight attack of diarrhœa." The operation occupied less than forty minutes.

In looking back at it I am inclined to think that the patient but for the ether might have left the table and resumed her calling. Certainly, the advantages over the other methods are evident, and I believe that even smaller stones would be much more easily removed by this method than by any other.

A CASE OF ANEURISM OF THE ARCH OF THE AORTA, WITH MARKED SYMPTOMS DEPENDENT UPON THE ANATOMICAL SITUATION OF THE TUMOR.

By JNO. B. DEAVER, M.D.,
DEMONSTRATOR OF OSTEOLOGY AND SYNDESMOLOGY, UNIVERSITY OF PENNSYLVANIA; SURGEON TO THE OUT-PATIENT DEPARTMENT OF CHILDREN'S HOSPITAL.

Mr. L., whose age is 49, occupation a paper-hanger, presents some form of mediastinal growth, the most likely, I think, to be aneurism of the arch of the aorta. When learning his history, I find he had acquired syphilis, which beyond doubt is one of the most fertile causes of aneurism. My idea in reporting this case is not on account of its medical interest alone, but more particularly from an anatomical point of view, as it serves to demonstrate how important it is for the medical man as well as the surgeon to have a thorough knowledge of topographical or regional anatomy, and particularly of visceral anatomy.

The diagnosis of mediastinal tumor has been made from the symptoms resulting from the pressure of the tissues surrounding the arch of the aorta. How can we tell when these surrounding tissues are pressed upon? First, by a knowledge of the relational anatomy of the parts, and, secondly, by a knowledge of their functions. In calling attention to the signs, symptoms, and their

most probable cause, I will mention the most prominent; first, the great amount of dyspnœa, the great distress in breathing when the patient attempts to lie down (orthopnœa), also while in this position the distention of the veins of the head, neck, and upper extremities, especially those of the left side, the harsh blowing breathing heard over the left chest posteriorly, the dry, hacking cough, which is made much worse when the patient attempts to recline, the œdema of left upper extremity, left side of head and neck, the œdema of feet and legs, the enlargement of the liver, the characteristic blowing sound heard over the course of the arch which is transmitted down the aorta and up into the carotids, the impulse communicated to the hand by making pressure on the sternum over the position of the arch. By passing over the supra-sternal fossa, pulsation of the arch is readily felt.

The dyspnœa is due, I think, to the enlarged and displaced heart. The position of the normal heart is in the middle mediastinal cavity, the greater part of it to the left of the median line of the sternum; its axis is obliquely from right to left; the base corresponds to the line of junction of the third costal cartilage with the sternum, and apex to the space between the fifth and sixth ribs, two inches below the nipple and one inch to its sternal side. In the case before us the axis of the heart is changed, instead of running obliquely from right to left, it runs directly downwards. The apex is at the bottom of the sternum, in the epigastrium; the base corresponds to the line of junction of the fourth costal cartilage with the sternum. The displacement, I consider, is due to the enlarged transverse portion of the arch of the aorta. To ascertain the cause of the suffocation when this man attempts to lie down, let us follow the course of the arch from its commencement and see what important tissues are in relation to it. The arch consists of three portions, an ascending, transverse, and descending. The first or ascending portion commences on the left of the sternum, behind the pulmonary artery, on a line with the junction of the third costal cartilage with sternum, the line corresponding to the base of the heart, from which point it proceeds upwards and outwards, to the right side, in the direction of the axis of the heart, till it reaches the lower part of the first intercostal space or the upper border of the second costal cartilage, when it turns to the left, becoming the second or transverse portion; this portion passes from right to left and from before backwards, about one inch behind sternum and one inch below upper border of the sternum, till it reaches the left side of the second dorsal vertebra, when it turns downwards to become the descending portion, ending at the lower border of the body of the fourth dorsal vertebra. Passing above the transverse portion of the arch from the left to the right, is the left brachio-cephalic or innominate vein, the vessel that returns the blood from the left side of the head and the neck, and the left upper extremity; passing over it is the left phrenic and pneumogastric nerves, the latter being the one that interests us in this particular case; beneath it is the bifurcation of the pulmonary artery and the left bronchus, and behind the trachea, œsophagus, thoracic duct, and the deep cardiac plexus of nerves. From the relation the transverse portion of the arch of the aorta bears to the trachea, it is very readily seen that when the patient lies down, that this portion of the vessel, if enlarged, would press upon the trachea, as the trachea bifurcates opposite the third dorsal vertebra, and the artery passes in front of the second dorsal vertebra, giving rise to orthopnœa, which is a marked symptom in this case.

Again looking at the relation this portion of the vessel holds to the left innominate vein, we have the explanation for the great distention of the veins of the left side of the head and neck, and the left upper extremity when the patient is in the horizontal position, and also for the œdema of these parts, for beyond question there is slight pressure constantly upon this vein. Within the concavity of the arch of the aorta is the left bronchus; this is pressed upon, the result of which we hear harsh and blowing breathing over the left chest posteriorly. The dry, hacking cough is purely laryngeal, there being no pulmonary trouble other than slight passive congestion at the bases of the lungs, and is caused by the pressure of the tumor upon the left recurrent laryngeal nerve. The recurrent laryngeal nerves, two in number, are branches of the pneumogastrics; the left recurrent nerve winds round the arch of the aorta, the right around the subclavian artery, first part, after which they ascend the neck in the groove between the trachea and the œsophagus to enter the larynx behind the crico-thyroid articulation; therefore it is very evident that enlargement of the transverse portion of the arch of the aorta would press upon the left recurrent laryngeal nerve, resulting in irritation of the parts supplied by this nerve, namely, the mucous membrane of the larynx. The enlargement of the liver and the œdema of the feet are due to the obstruction to the return circulation, a portion of which is effected by the pressure of the heart against the ascending vena cava.

1610 VINE STREET.

HOSPITAL NOTES.

GERMAN HOSPITAL, PHILADELPHIA.

(Service of DR. J. M. BARTON.)

LIGATION OF FEMORAL ARTERY FOR POPLITEAL ANEURISM.

(Reported by L. D. BROSE, M.D., Ph.D., Resident Physician.)

H. M., German, æt. thirty-five, married, laborer, gives history of primary syphilis, acquired in 1866. Last December he first noticed a swelling at the back of the right knee; this swelling slowly increased in size, throbbed, and was very painful; the patient, thinking he had rheumatism, on February 2 presented himself in the out-department of the German Hospital, suffering very much from an inflamed condition of this enlargement, so that he was obliged to use crutches. The outline of the swelling was much obscured by the existing cellulitis; but a marked expansive pulsation could be detected, occurring with the systole of the heart. The patient was advised to remain at home on his back until February 24, when he was admitted into the German Hospital. The aneurism could now be made out distinctly of a fusiform character, and measuring some

five inches in length. On auscultation, a distinct, rasping bruit could be heard occurring with the heart's systole, and transmitted a short distance below the tumor. The foot was swollen, very œdematous, and the pulsation in the posterior tibial, behind the internal malleolus, was hardly perceptible. Forced flexion of the knee failed in any manner to control the pulsation. The patient was placed in bed, and put on the tincture of veratrum viride, one drop every four hours. This treatment reduced the pulse rate from 104 to 84 beats per minute, but did not diminish the size of the enlargement.

February 27.—Dr. Barton resorted to compression of the femoral artery by means of bags of shot placed on the vessel and retained in position by a number of convalescing patients, who changed watch every hour. Twenty-two pounds were found after trial to be the smallest weight that would control the aneurismal pulsation. The compression was kept up for four hours, at the end of which time it was discontinued, owing to the incompetency of the assistants, who failed to retain the bags in position, thus allowing every few minutes a return of the circulation through the aneurism. Morphia, during this time, was freely administered to relieve the patient's sufferings. At the time of abandonment of the pressure, the patient was much exhausted and prostrated. The surface temperature of the limb, being taken every half hour, gradually fell from 97° to 94.4° at the time of our removing the shot. The axillary temperature on the morning of the compression was 99.1°, and the evening temperature 99.4°, the pulse also increasing somewhat in frequency. No perceptible impression was made on the tumor, and, on *March 1*, Dr. Barton again suggested a trial of shot compression, choosing as assistants Dr. Raab, the medical resident, the surgical nurse, a very intelligent man, and myself. The shot was increased to twenty-five pounds, and from 1.30 P.M. until 6.30 P.M. not a single pulsation went through the aneurism. The compression was kept up until 8.30 P.M., with almost equal success, when, no impression having been made on the tumor, it was discontinued, leaving the subject much prostrated and exhausted. Morphia, during this time, was again freely administered, and the patient encouraged to keep on with the treatment. The surface temperature was taken every hour; at two o'clock it registered 96.4°, and then gradually fell to 93.6° at five o'clock, and reached 92.3° at six o'clock. After this hour, the temperature rose, owing to several pulsations going through the aneurism, until at 8.30 the thermometer registered 95° Fahr. The axillary temperature on the morning of the compression was 100.2°, and the evening temperature 102.2°. The tumor continued increasing in size, now reaching some six inches in length, and at a consultation of the surgical staff it was decided advisable to ligate the femoral artery in the apex of Scarpa's triangle, under the Sartorius muscle. The patient was now put on nourishing diet, and prepared for the operation, which was performed *March 14*, Dr. Barton using the animal ligature and thorough antiseptic precautions. In making the incision, one small superficial vein was severed and secured by a silk ligature. The wound was brought together by a silver wire, reinforced by adhesive strips, and the patient returned to his bed with the leg carefully wrapped up in cotton batting. The patient came from under the influence of the anæsthetic, and was doing well, until between seven and eight o'clock, when I was called to allay an attack of vomiting. Examining the wound, I found it distended with blood; some five ounces had escaped, which appeared venous in character. The retching and vomiting being allayed, the bleeding discontinued of its own accord. The surface thermometer registered a temperature of 92.6° seven hours after the operation, and the axillary temperature was 97.2°. Next morning the clot in the wound was found to be very firm and much diminished in size, so that it was decided best not to open the wound, but trust to its reabsorption. During the day, the surface temperature ranged from 96° to 96.6°, the axillary temperature from 100° to 101°. The next two days the clot remained stationary, but on the third day it showed evidences of breaking down, the wound commenced discharging pus, and the surface temperature rising from 98° to 99.5°, with a corresponding rise in the axillary temperature from 100° to 102.5°. On the fifth day succeeding the operation, cellulitis manifested itself, the thigh becoming red, swollen, and much lymph being deposited around the seat of ligature. The lowest stitch in the wound being removed, a large amount of pus and broken-down *débris* of the clot escaped. Poultices were applied over the wound, dispelling the cellulitis and establishing a free flow of pus. From this date until complete closure of the wound the surface and axillary temperature gradually fell to normal, the patient making an excellent recovery, and was discharged from the house *April 22.*

The blood clot and the resulting pus deposits probably occupied a cavity entirely superficial to the artery. No portion of the ligature has been seen since its application, though the discharges were carefully examined for this purpose.

May 26.—The patient reported himself in the outdepartment, walking without artificial aid, the tumor having almost completely disappeared, and the lymph around the seat of ligature having been entirely reabsorbed. Since the moment of application of the ligature there has been no return of pulsation in the aneurism, but the pulsation of the posterior tibial, behind the internal malleolus, can not be detected in the operated limb.

VIENNA GENERAL HOSPITAL.

(Service of Prof. Bamberger.)

A CASE OF LEUKÆMIA.

(Specially reported for The Medical News.)

The patient, forty-nine years old, moderately thin, has suffered for a long time from cough and severe dyspnœa, is deaf in both ears, and gives as the cause of his sickness residence in a damp dwelling. The sick man lies in his bed in an apathetic condition, the red hue of his cheeks contrasting strikingly with the earthy color of the remaining portions of his body.

Examination gives the following condition: Tongue, coated; tonsils greatly enlarged; the mouths of the follicular glands covered with a caseous mass. The radial artery has undergone atheromatous change, is hard, firm, and tortuous. Large masses of lymphatic glands are found upon the neck, which are swollen, movable, resistent, but not painful. The axillary and inguinal glands, as well as those lying under Poupart's ligament, and generally termed Rosenmüller's glands, exhibit a similar condition. The ear-drum, in consequence of previous otitis media, is perforated upon both sides. The lungs are perfectly normal, as also temperature and urine. Heart and liver somewhat elevated. Area of cardiac dulness is increased in breadth. The spleen exhibits a particularly striking change; this organ has reached a size from seven to eight times its normal volume, and its inner, sharp, indented border can be distinctly palpated, while its lower, rounded border extends far beyond the left hypochondrium. That this resistent tumor, which has displaced downwards the lower portion of the abdominal contents, is the spleen, is proved by the fact that its motions are synchronous with respiration.

A drop of blood removed from the finger by the prick of a needle shows, under the microscope, an astonishing increase in the number of colorless blood-corpuscles. The white blood-corpuscles, finely granular, and differing in size, about equal the number of red corpuscles. It is plain from this cursory glance at the case that we are dealing with a case of leukæmia.

A moderate increase of the colorless elements of the blood occurs in a number of most diverse diseases, without causing important troubles. Intermittent fever, typhus, the puerperal process, alcoholismus, carcinomatous dyscrasiæ exhibit a relative increase in the white corpuscles. In such blood, acetic acid, formic acid, xanthine, and similar chemico-pathological substances are usually found. According to the locality of the formation of the white blood-corpuscle, it is customary to differentiate between a splenic, lymphatic, and myelogenic leukæmia. These different forms of the same general process occur in point of frequency in the order of their enumeration. In the majority of cases the first two forms are combined, but all three forms are united in our patient; for when we examine the bony system, although we find the bones of the cranium and of the extremities in normal condition, yet the sternum and single ribs are sensitive to very moderate pressure. Experience, moreover, has taught us that these are the bones generally affected in myelogenic leukæmia, and that it is very seldom that the long cylindrical bones are concerned in the production of white corpuscles.

The etiology of the affection is in most cases, as in this, very obscure, yet the fever dyscrasia seems to favor the origin of leukæmia. It is not at all necessary that leukæmic individuals should appear pale and anæmic; it occurs very frequently that their disease cannot be guessed at first blush. Patients complain most of dyspnœa, without there being any abnormality of the air passages or of the thorax demonstrable. This dyspnœa is usually explained by the diminution in number of red blood-corpuscles, which furnish to the system the necessary quantity of oxygen. This explanation is insufficient, because the paroxysmal nature of the attacks of dyspnœa in leukæmic individuals remains still obscure. Patients frequently suffer from œdema and continuous bleedings from the most different mucous membranes in this affection.

In the so-called pseudo-leukæmia we find, in fact, similar appearances. We find extensive swelling of lymphatic glands and enlargement of the spleen, but the colorless elements of the blood are not increased; consequently, a positive, differential diagnosis can only be made by the aid of the microscope.

Prognosis is unfavorable, perfect recovery has never been observed. Lethal result follows in consequence of inflammation of the respiratory organs, or of exhaustive hemorrhage and collapse.

Treatment remains for future discovery. The usual preparations of iron and iodoform, alteratives, such as arsenic, are altogether useless. Arsenic in the form of Fowler's solution is only useful in pseudo-leukæmia.

MEDICAL PROGRESS.

Two New Antiseptics.—M. G. le Bon has just presented to the Academy of Sciences two new and very effective antiseptics, the glyceroborate of calcium and the glyceroborate of sodium. Both of these compounds have the advantages of being very soluble, destitute of odor, and free from all toxic action. When exposed to the air they both deliquesce with great rapidity, absorbing from the air an equivalent weight of moisture. Both alcohol and water dissolve twice their own weight of these salts. They are powerful antiseptic agents even in very dilute solution; the most effective in a therapeutic point of view appears to be the calcic salt. It is absolutely innocuous, and it can be applied in strong solution to so delicate an organ as the eye without bad results. In a hygienic sense both can be employed with advantage as disinfectants and as preservers of meat and other alimentary products. M. le Bon has transmitted meat simply coated with a varnish of the glyceroborate to La Plata, and it has arrived in a perfectly fresh and sound condition. He thinks both salts will prove very useful as antiseptics in Lister's mode of dressing wounds.—*Lancet*, August 5, 1882.

Aphonia of Singers and Speakers.—For this affection Dr. Corson (*Revue Méd.*, April 12, 1882) recommends the patient to put a small piece of borax (two or three grains) into the mouth and let it dissolve slowly. An abundant secretion of saliva follows. Speakers and singers about to make an unusual effort should the night before take a glass of sugared water containing two drachms of potassium nitrate (saltpetre) in order to induce free perspiration. In similar circumstances this gargle may also be used:

℞.—Barley water, six ounces.
Alum, one or two drachms.
Honey, half an ounce.

Mix, and use as a gargle.

Or, again, an infusion of jaborandi, made by putting two scruples of the leaves in a small cup of boiling water, may be drunk in the morning before getting up. The free sweating is said very quickly to restore the strength of the voice.—*Practitioner*, August, 1882.

The Composition of the Urine in a Case of Cancer of the Liver.—Dr. V. C. Vaughan and Harriet C. Beringer give the following peculiarities observed in an analysis of the urine in a case of hepatic cancer:

1. The small amount of urine was due to obstructed circulation.

2. Urine in cancer of the liver deposits urates colored more or less of a red, and this color becomes darker on exposure to the air.

3. The formation of bile pigments continues even in structural diseases of the liver, which involve nearly the whole of the gland substance.

4. The formation of bile acid is arrested in the latter stages of cancer of the liver.

5. In this formation of bile the functional activity of the liver is concentrated for the most part upon the elaboration of bile acid.

6. Taurin and glycin are formed in the body even when the greater part of the liver is destroyed by abnormal growth.

7. Unoxidized sulphur (partly or wholly in the form of taurin) is present in the urine in large amount.

8. Their experiments indicate the two-fold origin of urea. The amount of urea is reduced to a minimum, and then remains stationary until death.

9. The quantity of uric acid is increased, and urates are deposited.

10. The phosphoric acid remains about the same in quantity as in health.

11. The sulphates and chlorides are greatly diminished.

12. Leucin and tyrosin appear and may be detected by microscopical inspection, after concentration, and may be approximately estimated by the method given. —*Physician and Surgeon*, August, 1882.

Purified Tow for Antiseptic Dressings.—MM. Weber and Thomas, of the French Army, assert that the desiderata of an antiseptic dressing for military

surgeons are—(1) absolute purity; (2) perfect whiteness and cleanness; (3) elasticity, smoothness, and softness; (4) great absorbent power, both of secretions from wounds and of antiseptic agents; it should (5) efficiently filter the air; (6) be antiseptic; and (7) cheap. They assert that they have prepared some purified tow which answers all these requirements thoroughly. Commercial tow is dirty, harsh from the presence of much woody fibre, and non-absorbent. This commercial tow is first dusted and tied tolerably firmly in packets, which are then soaked in water for twenty-four hours; they are then wrung out and placed in cast-iron pans, and a solution of caustic soda is poured on and kept just boiling for half an hour. The tow is then put into cold water and repeatedly washed until it has no action on turmeric paper. Subsequently it is immersed for half an hour in a solution of hypochlorite of sodium, and again washed in cold water as before. After soaking for twenty-four hours in cold water the latter is pressed out and the tow is plunged into dilute hydrochloric acid and left for half an hour, after which it is again washed in water and allowed to soak for twenty-four hours and then dried, after which it is carded in sheets or pledgets, or combed. Tow thus prepared is stated to be chemically pure, of perfect whiteness, soft, very elastic, readily absorbent, easily impregnable with antiseptics, and cheap. To render it thoroughly aseptic, it may be impregnated with either carbolic acid or iodine. For the former a solution of three parts of the acid in two parts of alcohol is sprinkled on sheets of filter paper, and these are laid between sheets of the tow and placed in a closed box. At the end of forty-eight hours the acid has all passed into the tow, in which it can be demonstrated under a microscope in the form of minute drops. MM. Weber and Thomas have prepared the carbolized tow of a strength of ten per cent., which they state to be an unirritating dressing and more than sufficiently strong of the acid for surgical purposes. To impregnate the tow with iodine, they expose it to the vapor until it assumes the color of roasted coffee. By similar means creasote, eucalyptus, etc., may be added to the tow. They state that, prepared in moderate quantities, the purified tow costs 1½ fr. to 1¾ fr. per kilo, or when carbolized 2 fr. to 2½ fr. per kilo.—*Lancet*, July 29, 1882.

Decoction of Onions in Milk in Dropsy.—Dr. Resquez claims to have obtained the greatest benefit in the treatment of various forms of dropsy by the use of a decoction of onions made by boiling in milk.—*L'Abeille Méd.*, July 17, 1882.

Persistence of the Ductus Arteriosus.—Dr. Malherbe (*Journ. des connais. Méd.*) cites several cases in which this malformation existed without producing characteristic symptoms during life, and enumerates, on the other hand, the symptoms which may fairly lead us to suspect it when they do exist.

The presence of a rough, prolonged murmur, systolic, or changing from systolic to diastolic, and having its maximum intensity at the level of the third left costal cartilage, and propagated up towards the left clavicle, justifies the diagnosis of persistent ductus. The murmur may be accompanied by either a general or a local cyanosis. It differentiates itself from that caused by an immediate communication between the pulmonary artery and the aorta, inasmuch as the latter produces a murmur of an intense thrilling character heard all along the hollow of the back, and loudest of all at the level of the transverse aorta (third and fourth dorsal vertebræ).

Persistent ductus is compatible with perfect development, strength, health, and long life.

One case quoted (age 28) was highly cyanotic, yet the patient was capable of severe and prolonged toil without respiratory difficulties. Another, a lady of 50, had never complained of anything leading to suspicion of malformation, which was only discovered post-mortem.—*Practitioner*, August, 1882.

Treatment of Lead Colic by Belladonna.—M. Bernutz has been repeating the studies of M. Malherbe as to the tolerance of belladonna in cases of lead colic, and he has found that as much as sixty centigrammes of the powder may be administered in severe cases, and when employed associated with purgatives, a prompt cure usually resulted.—*Rev. de Ther.*, August 1, 1882.

Fatty Tumors of the Palm of the Hand.—Lipoma of the palm is an infrequent but important affection. The diagnosis is attended with difficulty, for the tumors are often fluctuating; and in this, as well as their slow and painless growth and rounded outline, and the fact that they sometimes extend under the annular ligament, they resemble cysts of the synovial sheaths. When punctured, they do not yield fluid, but, on the contrary, a small pellet of fat may be extruded, which makes the diagnosis certain. The treatment is excision; but this should not be lightly undertaken, as in the palm these tumors do not grow from the subcutaneous fatty tissue, but from the fat under the deep fascia or between the muscles. Indeed, it has been suggested that in some cases they are developed from processes of the synovial sheaths of the flexor tendons, and are comparable with the arborescent lipoma of the synovial membrane of the knee described by Billroth. Great care must be taken to secure union of the wound by first intention, or the apparently simple operation may be followed by extensive suppuration in the palm and adhesion of the flexor tendons, with the result of a more or less useless member.—*Lancet*, July 29, 1882.

Albuminuria and Peptonuria.—The presence of albumen in the urine is not always due to renal disease, and in many forms of the latter it is often absent.

Albuminuria may be due to, 1. Increased arterial tension in the renal artery, producing active or passive hyperæmia; 2. Different parenchymatous diseases of the urinary organs; 3. Different fevers, such as typhus, variola, scarlatina, etc.; 4. Different diseases of the brain or medulla; 5. Poisoning by various substances, such as cantharides, carbolic acid, arsenic, morphia, alcohol, and phosphorus; 6. Irritation of the skin by thermal, chemical, or electrical agents; 7. Injection into the vessels or introduction into the stomach of large quantities of white of eggs, injection of defibrinated blood or water; 8. Sometimes in good health to violent exercise; 9. Renal ischæmia, compression of the renal artery, and intestinal catarrh; 10. Diminution of the quantity of chloride of sodium by transitory albuminuria.

Peptonuria is observed in profound disturbances of general nutrition, as in acute poisoning by phosphorus. It appears that in this disease the peptones do not come directly from the blood, but are artificial products developed in the uriniferous tubules and after the evacuation of the urine. The peptones result from the urinary digestion of the albumen by a process analogous to gastric digestion, as Brücke has found pepsin, and Potchin a special acid, in the urine, and as it has been found that the transformation into peptones is interfered with by alkalies and a reduced temperature.—*L'Abeille Méd.*, July 24, 1882.

Naphthaline as an Antiseptic.—Naphthaline has recently found a new and important use in medicine.

It has been found that this hydrocarbon is an excellent antiseptic, which kills fungi and bacteria in a short time. For surgical bandages and in contagious diseases, as far as experiments have been made, it has answered an excellent purpose, and seems well adapted to replace in many cases those antiseptics now so much used, namely, carbolic and salicylic acids, and iodoform. It has one great advantage over carbolic acid, being absolutely free from poison, and can therefore be used in any desired quantity without causing any disturbance. It also surpasses all other antiseptics in cheapness. As 100 kilos of pure naphthaline can be bought for 60 marks (about 7 cents per pound), there is no doubt that it will soon find general use for medical purposes.—*Scientific American*, August 12, 1882.

SYPHILIS CONVEYED BY SKIN-GRAFTS.—Another case in which syphilis was conveyed by skin-grafts is reported in Paris by M. FÉRÉOL. It occurred in the practice of M. Deubel; the patient was a man, aged forty-nine, who had not had any venereal affection, and who had a large wound caused by erysipelas with sloughing. Seventy-five dermo-epidermic grafts were put on, nearly all of which "took," and cicatrization was rapidly effected. A month after the application of the first grafts the cicatrix began to ulcerate in several places. Six weeks later an abundant roseolous eruption broke out over the body, and a month later mucous patches appeared in the mouth. One of the sons of the man, who had furnished grafts on each occasion, then consulted M. Deubel for mucous patches about the anus, and stated that eighteen months previously he had had a hard chancre for which he had not had any treatment. The case is apparently beyond all doubt, and shows the necessity for caution in the selection of persons from whom grafts are taken. The safest rule to follow is, wherever possible, to take the grafts from the person on whom they are to be implanted.—*Lancet*, July 29, 1882.

IODOFORM IN CHRONIC PULMONARY AFFECTIONS.—PROF. CHIARMELLI (*Giorn. di Clin. e Terapia et Gazz. Med. Ital., Prov. Ven.*, 1882), encouraged by the happy results obtained by Prof. Semmola with iodoform in the treatment of chronic affections of the bronchi, has experimented with this medicine during four consecutive years at the Hospital for Incurables, in many affections of the respiratory passages.

In phthisis, even at an advanced period of the disease with the presence of cavities, iodoform has given the author excellent results. In each case it diminished expectoration, and exercised a favorable influence upon the febrile manifestations. "Iodoform," he says, "diminishes the fever and affects the expectoration, which it not only diminishes in quantity but alters in character, preventing the putrefaction of its albuminoid elements. I am also convinced that the contents of the cavities in the lung exercise a powerfnl influence upon the production of hectic fever." In recommending iodoform in pulmonary phthisis, the author does not assert it to be a specific, but he claims that it arrests the march of this cruel malady and prolongs the life of the sufferer.

He also holds that in cases where caseous pneumonia is commencing, iodoform administered for a time proves efficacious in arresting the progress of the disease. With many individuals affected with chronic bronchitis and emphysema, it renders great service.

The formula which is employed is as follows:

Iodoform,	grs. iss.
Powdered lycopodium,	grs. viij.
Ext. of gentian,	q. s.

Make into 10 pilules. Take 3 to 5 in the day. If the dose is increased, gastric disorders supervene, and it is better to continue the above dose for a considerable time.—*Glasgow Med. Journ.*, August, 1882.

SPONTANEOUS RUPTURE OF THE STOMACH.—LANSCHENER (*Wiener Med. Blätt.*) reports the case of a woman, aged 70 years, who for a number of years had had an immense umbilical hernia. who, in an attack of vomiting after copious drinking of water, heard an explosion, experienced a sharp pain, and died in collapse in thirty hours. At the autopsy the small intestine and pyloric end of the stomach were found in the umbilical orifice, only the body of the stomach and the large intestine remaining in the abdominal cavity. In the posterior wall of the stomach there was a rupture more than one centimetre long; the abdominal walls seemed healthy.—*L'Abeille Méd.*, July 24, 1882.

ELECTRICAL TREATMENT OF ANGINA PECTORIS.—DR. LÖWENFELD (*Aerztl. Intelligenzbl.*, No. 39, 1881) relates a case of angina pectoris in which galvanization proved beneficial. The patient, a man aged 47, was subject to attacks of the disease occurring every month or two. These were characterized by excited respiration, oppression, small frequent pulse, sternal pain radiating to the left arm, and convulsive tremors of the limbs, and lasted about one hour. The heart was normal. The constant current was applied for one minute to each side of the neck along the course of the pneumogastric. The sense of oppression was immediately relieved. Ten such applications in the course of three weeks were followed by complete freedom from the attacks for more than two years.—*Practitioner*, August, 1882.

EXCISION OF THE TONGUE.—MR. CROLY, of Dublin, performs the following operation for cancer of the tongue, even when the disease is situated in the anterior portion of the organ: He first ligatures each lingual artery close to the hyoid bone, through a curved incision reaching from the symphysis down to the hyoid bone, and up and back to the angle of the jaw. Through these incisions he withdraws the tongue, as in Regnoli's operation, and removes the requisite amount of it by the benzoline cautery. Lastly, he divides the gustatory nerve where it lies along the inner border of the jawbone.—*Lancet*, August 5, 1882.

PUERPERAL INFECTION IN THE MALE.—DR. LAPONI reports, in the *Rivista Clinica di Bologna*, the case of a man who was infected with septic inflammation, after coitus with his wife, who was suffering from puerperal fever, and died seventeen days afterwards.

LUPUS OF THE LARYNX.—BREDA, basing his results on a great number of observations, to which he adds four occurring in his own practice, arrives at the following conclusions: Lupus of the larynx may be either primary or secondary to a similar affection of the skin, or nasal or buccal mucous membrane; it occurs most frequently in children (though a case in a man, aged 44 years, has been reported), and always in individuals of a lymphatic temperament. Males are less frequently attacked than females. In the larynx, lupus is most often found in the epiglottis, then on the aryepiglottic fold: in two cases only (Virchow, Thomas) did the process involve the trachea.

This disease is principally evidenced by affections of the voice, usually leading to complete aphonia. It is unusual to see it accompanied by any general nutritive disturbance; acute œdema of the larynx, threatening suffocation, may occur; oftentimes no troubles of deglutition or local pain are present.—*Journ. de Méd. de Paris*, August 5, 1882.

Atropia as an Antidote to Pilocarpine.—Dr. Frohnmüller reports a case in which the hypodermic injection of 0.02 grm. of the muriate of pilocarpine, in a man aged eighteen, with exudative pleurisy, produced exaggerated symptoms of pilocarpine poisoning; the administration of twenty drops of an atropia solution used for the eye was followed by an almost immediate disappearance of the symptoms. A number of experiments were then instituted, which show that this antidotal property is also possessed by homatropia.—*Med.-Chir. Centralb.*, July 14, 1882.

Iododorm in Toothache.—Schaff, in the *Deutsche Med. Zeit.*, No. 12, recommends iodoform, on account of its gently caustic action, as an anodyne application to exposed tooth-nerves. The circumstance that a single or repeated application of iodoform does not produce any irritation, much less any inflammation of the periosteum, and the double function of the remedy as a cleansing and disinfecting agent, make it especially appropriate as a caustic, particularly before the introduction of a temporary filling. The author uses a paste consisting of iodoform, powd., grs. 60; kaolin, grs. 60; carbolic acid, grs. 8; glycerin, q. s.; oil of peppermint, gtt. 10. Triturate the iodoform, kaolin, and oil of peppermint with enough glycerin to form a thick paste.—*British Med. Journal*, July 15, 1882.

Direct Transfusion of Blood.—At the meeting of the Société de Chirurgie, held July 19th, M. Roussel read a paper on an apparatus for direct transfusion of blood. This instrument was presented several years ago to the Société, but met with little favor; since then he modified it somewhat, and he now believes it fulfills all the indications.—*Gaz. Hebdomadaire*, July 28, 1882.

Congenital Malaria.—From a careful study of this subject Dr. Ch. Leroux derives the following conclusions:

1. It is as yet impossible to affirm the existence of a congenital form of malaria, or to establish the influence of heredity in infantile malaria. The reported cases are not numerous enough or sufficiently conclusive.

2. The existence, however, of certain cases of congenital hypertrophy of the spleen in children born of malarial parents, and in which the hypertrophy can be attributed to no other cause, together with the existence in such cases of other signs of malarial cachexia, render the existence of a congenital or hereditary form of malaria not altogether improbable.

3. Certain children appear to be born with an inherited predisposition to malaria, and may, even without being directly exposed to external malarial influences, suffer from an intermittent form of fever from the time of their birth of a type similar to that existing in the mother. There is considerable reserve expressed as to the share due to heredity in the production of these cases. Further researches are necessary.—*Rev. de Méd.*, July, 1882.

Nutritive Injections.—Dr. Morrel Mackenzie recommends the following combination:

Boiled Beef, Mutton, or Chicken,	℥iiiss.
Sweet-bread,	℥ij.
Fat,	℥v.
Brandy,	℥ij.
Water,	℥iiss.

The meat, fat, and sweet-bread, should be minced very fine, and then passed through a sieve. The injection should be warmed up to 32°–35° C. before use, and should not be given oftener than twice in twenty-four hours: the rectum should be washed out with warm water before the injection is administered.—*Journ. de Méd. de Paris*, August 5, 1882.

Ligature of the Femoral Vein at Poupart's Ligament and Lateral Ligature of Veins.—At the eleventh annual meeting of the German Surgical Society, held in Berlin on May 31, Braun, of Heidelberg, advocated the ligation of the femoral vein at Poupart's ligament, since of the twelve cases reported of this character, in only two did any results of obstructed circulation appear, while the ligature of the femoral artery is only necessary when the ligature of the vein fails to control the hemorrhage. Braun also stated that the danger of thrombosis or slipping of the thread in lateral ligature of veins was over-estimated.—*Berliner klin. Woch.*, June 12, 1882.

Action of Pilocarpine on the Heart.—M. Schuk has analyzed the action of pilocarpine on the heart, and thinks that it cannot be regarded as an active heart poison, as it is only capable of arresting the heart in a 1.25 per cent. solution. And even in this dose the ganglionic apparatus alone is acted on, the muscular fibres remaining unaffected. Atropia is capable of effacing the retarding action of pilocarpine. The effects produced by pilocarpine are proportionate to the dose, a point of contrast with the action of muscarine and atropia. The pulsations of all parts of the frog's heart are arrested by pilocarpine in large doses. —*Centralb. f. d. Med. Wissen.*, No. 20, 1882.

Extract of Convallaria Maialis as a Diuretic. —At the meeting of the Société de Therapeutique, held July 26, M. Moutard-Martin read notes of a case in which the administration of the extract of convallaria, when associated with chloral, produced marked diuretic effects, while neither alone produced any change in the quantity of urine passed.—*Gaz. Hebd. de Méd. et de Chirurg.*, August 4, 1882.

The Effects of Depression of the Cranium.—In an elaborate memoir on the subsequent effects of depression of the cranium in childhood, Dr. Guermonprey draws the following conclusions:

1. Depression of the cranium, whether complicated or not, can, in a general manner, be the cause of various psychical disturbances.

2. These disturbances are more important when the depression is located in the frontal region, particularly on the left side.

3. The depression may act as an interference to the normal development of the psychical function and growth of the brain.—*Arch. Gén. de Méd.*, Aug. 1882.

Poisonous Effects Produced by the Topical Use of Iodoform.—Mr. Henry E. Clark reports a case of poisoning from the topical application of iodoform to a sinus, the result of a chronic abscess in front of the hip-joint. The symptoms in this case, as in most of the recorded cases of iodoform poisoning, although they vary considerably, have certain features in common which it is well to discriminate. Thus, in all there is pyrexia marked by extreme irregularity, the temperature running up to 104° F., or even more, and falling again very rapidly to near normal; the rise invariably takes place in the evening, but the morning fall is nearly always out of proportion to the evening rise. Thus, in the case under notice, the temperature on the evening of the 11th May was 103.8 F., but fell the next morning to 99.4 F., to again rise the following evening to 102°. Again, on the 16th, evening, it was 102.6°, and the following morning it was normal; but again rose to 102.4° at night. The pulse is extremely rapid and feeble, its rapidity being in great measure independent of the rise of temperature—for in our case it was noted that the pulse beats were 140 per minute on the 13th, morning, when the temperature was nor-

mal. Nausea, vomiting, and loss of appetite are invariable symptoms, the vomiting being persistent and very little relieved by treatment. In the case detailed this symptom continued for more than a fortnight in spite of remedies, and the vomited matters were of viscid consistence and greenish color. There is always lassitude, headache, and dulness of intellect, and often delirium, which in the worst cases passes into unconsciousness, or is followed by localized paralysis. The symptoms sometimes resemble those of acute meningitis, the patient uttering peculiar cries, rolling his eyes, and the headache being intense, It is curious that although iodoform is so freely used in a great variety of conditions, and in patients of all ages and constitutions, it so seldom happens that constitutional effects are produced, and we are led to ask what are the circumstances which predispose to the absorption into the system, and the production of general symptoms. Mundy holds that the large quantity employed is the chief factor, and speaks of cases where from 2½ ounces to 10 ounces have been employed at one dressing; certainly in our case we could not blame ourselves for the reckless employment of the drug, as only five grains were applied on each alternate day. Another point, however, to be noted is the condition of surface to which it is applied; thus, on a free surface where a great deal of the iodoform is carried into or through the dressing by the discharge, the risk of absorption will be less than in a sinus with only one external opening where the discharge is pent up and the iodoform may be retained for many days. Nor must it be forgotten that some granulating surfaces are more active than others in absorbing materials from without, healing burns being especially adapted for absorption, which may account for the number of fatalities where this drug has been employed in the treatment of burns. —*Glasgow Med. Journ.*, August, 1882.

The Total Volume of Blood in the Body.—MM. Grehant and Quinquand have endeavored to improve on the present inexact methods of determining the volume of blood in the body.

Claude Bernard established that the oxide of carbon when united with hæmoglobin formed a much more stable compound than oxy-hæmoglobin, and that oxide of carbon would displace its own volume of oxygen.

The total volume of the blood can therefore be obtained by allowing an animal to breathe a certain quantity of gas containing a known proportion of carbon mon-oxide. Then on measuring, say a quarter of an hour afterwards, the volume of carbon mon-oxide remaining, the volume absorbed by the blood can be readily estimated. On the other hand, the amount of mon-oxide fixed by a given volume of blood can be determined by measurement before and after the poisoning. Knowing the volume of gas absorbed and the quantity fixed by 100 c.c. of blood, the entire volume of blood can be obtained by a simple proportion. They do not give, however, any results of these examinations.—*Revue Scientifique*, June 10, 1882.

The Alkaloids of Pao Pereira (*Geissospermum lævе*).—E. Czerniewski, in an inaugural thesis, reports the results of a careful study of this subject, especially in its relations to toxicology, as follows:

1. From acid solutions geissospermin is extracted by benzole and chloroform, pereirin only by chloroform; from alkaline solutions geissospermin is removed by benzole, chloroform and amylic alcohol; pereirin by petroleum, ether, benzole, and chloroform.

2. Geissospermin is distinguished from strychnia by the fact that it is taken up by its solvents from acid solutions, by the reaction with Frœhde's reagent, and by the physiological test.

3. Pereirin may be distinguished from brucia by the fact that chloroform removes it from acid solutions, by its reaction with gold chloride, by its behavior with nitric acid and stannous chloride—in which reaction a striking similarity between the two alkaloids is also shown—and by the physiological test.

4. Geissospermin is rapidly absorbed from the alimentary canal, and is eliminated by the kidneys. The elimination reaches a maximum rate in from 24 to 72 hours.

5. Pereirin is readily absorbed from the intestines, but is apparently for the most part decomposed in passing through the system.

6. In a forensic analysis, geissospermin is to be sought in vomited matters, in the stomach, small and large intestines, liver, feces, and urine. Pereirin is to be looked for in vomited matters, in the stomach, small intestines, blood, liver, and lungs.

7. The following reactions of pereirin are especially worthy of note:

(*a*) The red color produced on adding to its solution in dilute sulphuric acid a solution of potassium bichromate.

(*b*) The red precipitate produced by gold chloride.

(*c*) The non-appearance of a red color on warming with mercury nitrate.—*Detroit Lancet*, August, 1882.

Tubercle of the Synovial Sheaths of Tendons.—MM. Terrier and Verchère describe a tubercular disease of the synovial sheaths of tendons, which appears to be more common in the hand than any other part. The tubercular nature of the affection in the cases they report is demonstrated by the microscopical characters of the inflammatory growth and the concomitance of tubercular disease of the lungs. Premising that the disease may be secondary to tubercular affection of neighboring bones and joints, they draw special attention to the form which occurs primarily in the synovial sheaths. They describe the origin of the affection as insidious, and the progress as very chronic. The first symptom is a swelling over part of a synovial sheath, as, for example, over the palmar surface of a phalanx. This swelling gradually grows and becomes softer, movement of the part then becomes both painful and limited. Other like swellings appear over other portions of the synovial membrane, as in the palm of the hand and above the wrist. The skin becomes adherent, reddened, and ultimately ulcerates, and pus and sero-pus are discharged; the ulcer extends, its edge being irregular, thin, undermined, and livid. A probe passed to the bottom of the ulcer readily finds a narrow opening into the sheath, along which it may be passed for some distance. The tendons do not slough, nor do they become firmly adherent. The disease does not spread to the neighboring bones and joints; and although in its course more than one part of the synovial membrane is affected, these are separated by quite healthy portions of the membrane, and this fact forms one of the best diagnostic features by which it may be distinguished from fungous disease of the membrane, in which the whole extent of the sheath is always involved. In one of the two cases observed by the authors, there was a very distinct history of an injury as the exciting cause: the patient, a young woman, had cut her wrist severely, and in another case there was a history of a bruise. The constant and rapid movements of the hand are considered to account for the great frequency of the disease there. The only treatment which promises any good seems to be early free removal of the tumors; cases in which this was done with good effect by Trélat and by Bouilly are recorded in the paper before us in the July number of the *Revue de Chirurgie*.—*Lancet*, July 29, 1882.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE, ... $5.00.

SINGLE COPIES, ... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made at the risk of the publishers, by forwarding in REGISTERED letters.

Address, HENRY C. LEA'S SON & CO.,
NOS. 706 & 708 SANSOM STREET,
PHILADELPHIA, PA.

SATURDAY, AUGUST 26, 1882.

CONVULSIONS IN CHILDREN.

INFANTILE convulsions must always possess for the practical physician a keen, almost a fascinating, interest. The cases are by no means of equal importance—some may be immediately dangerous to life; some may be merely symptomatic of diseases varying immensely in severity, and some may possess but little significance. As regards the symptom—convulsion—the phenomena are various. The convulsions may be general, and involve all the muscles of animal life, or they may be limited to a single group of muscles. The symptomatic and the therapeutical diagnoses demand the clearest conception, the greatest fertility of resource, and the utmost promptitude of action.

As above suggested, a convulsion may mean much or little. At the outset, it is best to have as definite a conception as possible of what a convulsion is. That the pons Varolii and medulla oblongata are centres of reflex actions has long been known, but it was reserved for Nothnagel to demonstrate the position and define the limits of the "spasm centre." Irritation of this centre induces general convulsions, and this irritation may be direct or reflex, centric or excentric. The results of experimental physiology receive support from pathology. Ladame, in his *Hirngeschwülste*, has formulated this conclusion: When the symptoms of brain tumor exist, if there are convulsions, the tumor is not in the medulla, which may be interpreted as follows:

When a tumor develops in a position to injure the *spasm centre*, convulsions become impossible because the injured part has lost its power to functionate.

Various causes increase the irritability of the spasm centre. Abnormal irriatbility may, indeed, be hereditary. It is well known that certain families exhibit the tendency to convulsions, and all the children may experience attacks, or they may be confined to one sex. This tendency may be so strong that infants in the womb are affected, but it is in the first two years of infantile life that the greatest irritability of the spasm centre is found to exist. Beside this tendency, which is inherited, various constitutional states increase the liability to attacks of eclampsia. Rickets has a prominent position as a pathogenetic factor. This state acts, probably, by so increasing the irritability of the centres of reflex action, that very slight peripheric irritation sets off the high-strung spasm centre. The state of nutrition of the child is not without influence. When much reduced by long illness, the reflex functions are correspondingly lowered, and hence when, under such circumstances, convulsions occur, it is reasonable to suppose that no peripheric irritation has sufficed, but that some "coarse lesion" of the intra-cranial organs is the cause. Hence it follows that the nutrition of the child suddenly attacked with convulsions has diagnostic value; if the child be fat and healthy, the convulsion is a symptom of some excentric irritation; if weak and emaciated, it signifies some centric lesion, notably tuberculosis. It is not affirmed that such a rule has no exceptions—only that it has diagnostic value.

It is important to distinguish between eclampsia and epilepsy. Age is an influential element. If a convulsion occur after four or five years of age, if it is over in ten minutes, and no cause can be discovered for it, these constitute good grounds for suspecting epilepsy. If the attack is accompanied by high fever, if albumen can be detected in the urine, or if some acute disease follow, the seizure is one of eclampsia, although the patient may be anywhere from two to ten. Again, the character of the attendant phenomena—the behavior of the convulsion itself—throws strong light on the diagnosis. When the convulsions are limited to the face, to one limb, to one side of the body, it may be concluded that the lesions are intra-cranial. Again, if any part, the seat of convulsion—the face, the limbs, etc., should continue paretic or paralyzed for some days after the seizure, or if a squint should continue, or an eyelid droop, or the pupils remain unequal, cerebral lesions probably exist.

The prognosis of convulsions is usually difficult. When arising from intra-cranial lesions, the prospect is gloomy. Such evidences of cerebral mischief as squinting, irregular pupils, coma, etc., are of evil omen. In the convulsions due to uræmic poisoning, the most unfavorable symptoms may be recovered from, but the case wears a less hopeful

aspect the more persistent the failure of the urinary excretion. When the breathing continues labored, and there is deep cyanosis, with lividity of the face and the pulse is very rapid, the case has a most unfavorable appearance. A convulsion at the onset of an acute affection, as scarlet fever, affords no certain indication of the future gravity of the disease, but does illustrate the mobility of the nervous centres. Convulsions occurring toward the close of an acute disease, are unfavorable, and often signify that the disease has taken a more serious direction, or that tubercular meningitis has come on. In some children, so irritable and mobile is the reflex centre of spasm that but trivial peripheral impressions suffice to bring on convulsions. Amongst such causes, are indigestible food, swollen gums, earache, etc. Such children may have repeated attacks, which, if known, must lessen the gravity of the prognosis. A guarded opinion should be given as respects the future condition of such children, for if convulsions occur readily during the first and even second dentition from slight causes, this is a reason for apprehending the subsequent occurrence of epilepsy. Habit is such an influential factor in determining attacks of nervous diseases that we may well be solicitous regarding its power here.

The treatment of convulsions has an importance determined entirely by the cause of the seizures. Is the attack merely an excited state of the spasm centre from simple peripheric irritation? Has the child eaten some indigestible food? Are there worms, irritating foods, scybala, etc., in the intestinal canal? Is there a stone in the bladder, preputial irritation, or other source of irritation in the genito-urinary tract? Has sufficient urine been passed, and is the urine albuminous? Is an acute disease beginning, and is fever present? Has the child passed through an illness recently, especially of scarlatina or whooping-cough? Is the child emaciated? Has the child rickets? The treatment is much influenced by the answers to these questions. Causes of irritation must be at once removed by emetics, purgatives, vermifuges, etc., as required. Then follow the measures to allay the excitability of the spasm centre; bromide of potassium, chloral hydrate, and the inhalation of chloroform. When time presses, the last-mentioned expedient has great value. It is sometimes advised to administer ether instead of chloroform, but this suggestion indicates a failure to appreciate the excitant qualities of the former. Chloroform is well borne by children, and is more effective than ether. Chloral, by the rectum, renders an incontestable service. It is safe in the case of children; it is effective, and although not so prompt, is more sustained in action than chloroform. Bromide of potassium is most useful after consciousness is restored to prevent future or impending attacks, or to allay the excitement, muscular twitching, etc., which may indicate the onset of convulsions. When swallowing is impossible, bromide may also be given by enema, and it may be combined with chloral for all of the purposes to which the latter is applied. If the surface is cold, the circulation feeble, and the skin dry, the child should be put in a bath at 100° Fahr. If the same conditions exist with a moist and clammy skin, dry heat should be used, the articles affording it having a temperature of 100° also. If, on the other hand, the temperature of the child is high, reaching 103°, 104°, or 105°, or more, the cold bath, or the cold wet pack should be employed without hesitation. The character of the bath prescribed will necessarily be affected by the state of the urinary secretion. If it is necessary to compensate in an increased action of the skin for the diminished activity of the kidneys, a warm or vapor bath may be necessary. If albuminuria exists, and the urine is very scanty, the convulsions being distinctly uræmic, a very powerful action of the skin must be secured, and this can be effected by no measure so successfully as by pilocarpine. There can be no doubt of the great good accomplished by this remedy under these circumstances, but any prudent practitioner will avoid inducing a dangerous cardiac depression by the use of large doses. Compensation for the diminished urinary secretion can also be obtained by free catharsis.

We should not fail to mention the remarkable results obtained by Loomis in cases of uræmic convulsions, by the hypodermatic injection of full doses of morphia. Although such treatment has been applied to adults only, and may be inadmissible in children, it throws light on the therapeutical diagnosis. In the simplest cases, almost no treatment may be required. A child has eaten an indigestible meal, has a convulsion, and vomits freely. The stomach emptied, the nervous disturbance ceases, but it is always well in such cases to prescribe some bromide of potassium to allay the reflex irritability and the excitement of the spasm centre. Here, as under all circumstances, no treatment should be instituted that is not the result of a careful survey and a logical deduction from the facts.

"OUR POOR FEET,"

So Mrs. Haweis, in her "Art of Beauty," well entitles one of her chapters. The "Crusade against Fashion" seems to be growing in importance and vigor. A century ago Camper, Professor of Medicine at the Hague, took up the task, and now not only a lady, but well-known scientists, are entering the lists, and they are lances that count for something. Mr. Flower, in his "Fashion in Deform-

ity," in England; Onimus in France; Starke in Germany; and Dr. Benjamin Lee in this country, have treated the subject in scientific papers of value. The war has been carried also into Africa. Such good surgeons as Mr. Treves, of London, and Mr. E. Noble Smith—the latter at the request of the National Health Society—have addressed public meetings on the evils of our modern dress. The *Medical Times and Gazette* intimates that such reforms had better be left to men of smaller calibre, as if the subject were beneath their dignity. But when we see that Mr. Flower and Mr. Spencer Wells do not regard it beneath their dignity to preside, or Dr. Clark to speak, at such meetings, or foremost scientists to write on the subject; and when we think of the importance of the matter as to health and to comfort, we hail the omen as auspicious. Men of small calibre would not gain the public ear. Wellington's first care was that his army should be well fed and well shod. Sir Henry Thompson has shown us how to cook beans; why should not Onimus show us how to make shoes?

It may be that the ladies will consult their *modistes* as to the size of their waists, and both sexes their shoemakers as to the shape of their shoes, rather than flee to the doctor, only to be met with a stern rebuke. But what if we could get the ear of the *modiste* and the shoemaker, and make the natural the fashionable, or convert by fortunate chance a Mrs. Langtry to the idea that natural forms are not ugly, and that the Venus de Milo and the Apollo Belvidere are at once models of health and of beauty? But be it as it may, it is our duty to cry aloud, and if society and the shoemakers will not hear—*tant pis!*

Savages do not deform the feet. Only the semi-civilized and the civilized do. We often hold up our hands in horror at the Chinese. Were it our feet—we would soon cease holding them up. Look in the *Popular Science Monthly* at Mr. Flower's latest Paris shoe for women, or at the outlines of the natural foot with those of a shoe dotted over it, or at his only too faithful pictures of common deformities of the foot seen every day at our hospitals, and then say whether the Chinese are very much ahead of us, *quoad* the feet.

But let us see the actual troubles in detail. They are of two kinds, first, as to the axis of the sole, and, secondly, the kind of heel. The Waukenphast shoe follows very well the curved axis of the foot-sole, as Dr. Lee has shown. But ordinary shoes have a median straight axis with nearly symmetrical curves on each side, barely varied enough at the "waist" to make them rights and lefts, and at the toes it is an evenly bevelled wedge, as if, as Mr. Dowie says, "the human foot had the great toe in the middle and a little toe at each side like the foot of a goose"—which, indeed, it too often is.

The result is that the great toe is bent obliquely outward, often overlapping the others, and a bunion soon forms at its knuckle-joint; the other toes are crowded together so that the little toe is pressed tightly inwards, followed by one or two quickly developed corns; and at least one of the other toes, to find room for itself, either overrides its neighbors or is overridden by them, and not seldom has to be amputated to make walking to any extent a possibility. In-growing toenails also often result from this pressure.

The effects of slight continuous pressure, as shown in the grooving of hard bone by a soft elastic artery, all doctors know, so that we may well believe, with Mr. Flower, that even the stockings should be rights and lefts, and in some cases made like a glove with compartments for each toe. In fact, he says, a normal foot can scarcely be found.

Who does not admire a baby's foot or that of an antique statue? Notice the wide-spreading toes, the large inter-space between the great toe and the second, the almost independent mobility of every toe, and especially of the great toe with its seven muscles. Verily if women would only heed the lesson and show a really natural and pretty foot, they would add, as Mrs. Haweis says, a dangerous arrow to their quiver of charms.

But the other evil is equally bad, and is especially and almost exclusively a woman's danger. The heel is made too small and too high, and is displaced forward. Its narrowness makes women unsteady in their gait, like the Chinese. Their equilibrium is unstable. Its height is still worse. It puts the sole on an inclined plane as if the wearer were constantly going down a mountain; and how fatiguing that is let any one say after a trial. It predisposes to falls. The foot sliding forward on to the toes doubles them up producing painful corns on their upper surface. It throws the weight on the forefoot instead of the heel. Onimus shows by the graphical method, to which we lately alluded, that this twists the axis of the foot inward and often produces painful contractures of the calf muscles, the anterior tibials, and even the muscles of the thigh, due to the extra work required by the abnormal posture to maintain the body in equilibrium, and prevent it from falling forward. Especially is the peroneus longus muscle put on the strain by these two defects. Let any one stand bare-legged on one foot, and watch the tendons of these muscles in a looking-glass as his equilibrium is disturbed. Every slight want of balance causes one or another to spring into strong relief, showing their vigorous contraction. Imagine this going on all day in both feet, and one can readily believe that walking and

especially running (well-nigh a lost art among corset-bound and Chinese-shod women) will be rarely indulged in except when necessity admits of no excuse.

These evils are rendered even worse by the absurd displacement of the heel forward. This shortens the base of support thus increasing the instability of the gait, and transfers the point of support from the heel to the arch of the sole, where, instead of a large, solid, well-padded bone to bear the weight, we have a series of small bones and joints, ill protected from the blows attending each step; and the result is a frequent chronic slight inflammation of these joints which makes the foot tender and constantly uncomfortable.

The effects both on health and temper of evils such as we have described, the tendency to a sedentary life and sedentary pursuits, the unfitness for athletic sports involving the free use of the legs and feet, are evident to all but the devotees of fashion. But the evil consequences do not stop here. The respiration and the circulation are impaired, the nervous system suffers, and Onimus even believes that many displacements of the uterus result from the change in the centre of gravity.

Shoes that are natural in shape and healthful in use need not be ugly. But this is not so much a question of fact as of fashion. We would not now deem beautiful the very long shoe, with its hay-stuffed toe, worn by the gallants of the fifteenth century. Mrs. Haweis has suggested—and the suggestion is worth heeding—whether the Greek sandal could not be re-introduced with advantage both to health and looks, while the feet could be protected in our more rigorous winters by substantial and pretty stockings of worsted, silk, or velvet. Her further suggestion that wooden pattens be substituted for rubbers and arctics, at least in wet and mud, has not only novelty, but has given rise to suggestions of form and of ornamentation that are not to be despised. In time, with the æsthetic idea upon us as at present, we may see shoes and sandal-straps, pattens and boots rival in ornamentation those of Chaucer's parish clerk with "Paules windows carven on his shoes."

Now that M. Burq has passed through the stage of denial of his method of metallotherapy, he is assailed with the criticism that it is not new—that he has simply revived Perkinism. In a recent discussion before the Biological Society of Paris, Rabuteau stated that Perkins was the real discoverer of metallotherapy, and that Burq had merely popularized it. But Rabuteau has certainly heard only of the "metallic tractors," and has not investigated Perkins' method. By the use of a metal cylinder, applied to various parts of the body, Perkins pretended to cure all kinds of diseases. In a work published in London, at Perkins' Institute, a copy of which is before us, we find the claims of the inventor of the "tractor" set forth, attested by a number of certificates of cures. There is not a word in this work about the peculiar phenomena of metallotherapy—of the influence of metals on hemi-anæsthesia, of transfer, etc. The two agree simply in the application of metals, but whilst Perkins used his metal tractor as a magician's wand for curing disease, Burq discovered the influence of some metals on the sensory and motor functions of certain hysterical subjects.

RABUTEAU has recently been studying the effects of the sulpho-carbolate of sodium as a purgative. He finds that this salt is a certain and agreeable purgative, and possesses the distinct advantage over the sulpho-vinate, which has been warmly recommended for the same purpose, that it is a stable salt and does not decompose in the air or in aqueous solution.

SOME time ago the London *Lancet* entertained its readers with a letter from a special correspondent in America, who pictured the low state of medical education in this country by asserting that one might graduate from some of its best schools without having seen a clinical case. The unfairness of the assertion, and the false inferences that might be drawn from it, were pointed out at that time on this side of the water. But now the *Lancet* brings to its many American readers a new wrinkle in the methods of medical education. The Yankee student has not been smart enough to get off easier than his British fellows after all. The latter have a way of getting degrees that saves them the trouble not only of studying clinical cases, but also of studying at all.

Before the General Council of Medical Education and Registration, on June 27, Mr. Macnamara brought up the matter of "personation" at examinations. "Some time ago," he said, "it came to the knowledge of the branch Council of Ireland that £200 had been offered to a practitioner by a student to pass some of the examinations for him, so that his name might be in the medical register." Another student, it seems, who had passed first at a preliminary examination, was not in the country at the time. One gentleman (?) passed for himself and three others, and "a most successful grinder" kept a student for the purpose of passing preliminary examinations. It appears from the report in the *Lancet* that these little obliquities were practised to gain the fascinating title of L.K.Q.C.P.I.

IN another column (page 250) we give extracts from a published letter of Dr. J. T. Baldwin, lately

Professor of Anatomy in the Columbus Medical College, and the statements therein contained are so direct, and of such a grave character that if not promptly and fully refuted must seriously affect the standing of the Columbus school, and may even render its faculty amenable to the provisions of the Act of February 12, 1881, which declares that to give a diploma to one who has not attended a full course in the institution granting the diploma, is punishable with a fine of from one hundred to one thousand dollars, or imprisonment in the penitentiary for from one to three years, or both.

REVIEWS.

Transactions of the American Gynecological Society. Volume VI., for the year 1881. Philadelphia: H. C. Lea's Son & Co., 1882.

We are glad to welcome the receipt of this volume at a much earlier period of the year than when that of 1880 appeared. If the contributing Fellows will only act upon an excellent suggestion made last year, and present their papers in a finished state at the fall meeting, we have no doubt that there will be nothing wanting, on the part of the Secretary, to have the volume ready for the press at a much earlier date still—possibly in the spring months. It is not desirable to very largely increase the fellowship of the Society, as such a body should consist mainly of the working gynecologists of America; but an addition of twenty by election in six years seems hardly enough to embrace the element desired. The most certain plan to secure the services of a full corps of contributors would be to issue the transactions at as early day as possible. Writers who are anxious to see their papers in print, in this day of weekly medical journals, are not willing to wait several months for their publication, when periodicals are ready to take them upon much more favorable terms. The size of the volume under notice, 542 pages, indicates no falling off, as yet, in the activity of the working Fellows; but the experience of other societies points to a future time when such a result may be expected, unless the number on the roll shall be considerably increased. The plan of holding the meetings only in the cities of Boston, New York, Philadelphia, and Baltimore, is a wise one, as it secures a large attendance, and excites a much greater interest in the minds of visiting physicians. The experiment of going to other cities than these has been tried, but the result was not encouraging. The day may come when it will be found of advantage to meet always in one city, and the same building, which shall contain a collection of books and curiosities belonging to the Society: but this will require a handsome legacy to put it in force.

The subjects treated in the volume for 1881 are, Acute hyperæsthesia of the peritoneum, following minor gynecological operations; Exploratory puncture of the abdomen; Cases of pelvic effusion resulting in abscess; Genital renovation in urinary and fecal fistulæ; Forcible elongation of pelvic adhesions; Lupus of the vulvo-anal region; Bursting cysts of the abdominal cavity; Erysipelas in childbed, without puerperal peritonitis; Expansion of the bladder over abdominal tumors as a complication of laparotomy; Fibroid polypus with partial inversion of the uterus; Axis traction with the obstetric forceps; Measurements of the uterine cavity in childhood; Jaundice in pregnancy; The practice of gynecology in ancient times—fourteen.

The papers contributed by candidates for fellowship are upon the following subjects: Prevention of laceration of the cervix; A point in the management of the first stage of labor; The treatment of chronic perimetritis by puncture and iodine injections; The mechanical action of pessaries; Mania lactea, with reports of two cases; A contribution to the history of combined intra-uterine and extra-uterine twin pregnancy—six; of these, four were from New York, and one each from Chicago and Baltimore. Of the fifty-four Fellows of the Society, thirty-six reside in Boston, New York and Brooklyn, Philadelphia, and Baltimore; one third of the whole fifty-four coming from New York and Brooklyn.

The volume of 1881 will compare well with any European production upon the same class of subjects. It is not too much to say, that it has no superior in the English language, either in material or finish, as a society's transactions.

CORRESPONDENCE.

THE JUBILEE MEETING OF THE BRITISH MEDICAL ASSOCIATION.

Worcester, Wednesday, August 9, 1882.

The jubilee of the British Medical Association was held to-day, but a large number of the members came to the loyal city of Worcester yesterday. The city is gay with bunting, and is evidently *en fête* to receive the medicos, who are here to the number of nearly six hundred, among whom I have already noticed Dr. Austin Flint and Dr. F. S. Dennis, of New York, both of whom are very well known and very popular with us. Worcester is the birthplace of the Association, which was started just fifty years ago by Sir Charles Hastings and a few trusty helpers. Then it was called the Provincial Medical and Surgical Association, and its numbers were few. Now it is a mighty Association, with nearly 10,000 members on its roll, an annual increase of several hundreds, and a rich balance in the hands of the Treasurer. The meeting opened yesterday afternoon with a special service in the Cathedral and a sermon by the Dean on the existence of a Personal God. Closely following this was a dinner given by the Mayor to the officers of the Association and a few distinguished visitors. Then, at 8 P.M., the President for the year, Dr. Strange, of Worcester, was inducted, and delivered his Address on the Revival and Survival of Medicine.

Taking a retrospective glance at the field of medicine, the President observed: "Both at home and on the Continent of Europe that decade was distinguished by a galaxy of names the like of which, at one period of time, the world has rarely if ever seen. There were, indeed, giants in those days. Recall to your minds the names of Wilson Phillip, who once lived here in Worcester; of Lawrence, of Abernethy, and of Cooper, all of whom, however, were already passing away; and then of Copeland, of Latham, of Marshall Hall, of Brodie, and of Watson, in England; of Barclay and Gregory, the Munroes and the Thompsons, of Knox, Alison, Bell, and Christison, in Scotland; of Graves, and Stokes, and many others, in Ireland. Nor was the Continent in any way behind us. I myself had the pleasure and advantage of hearing Louis expound Laennec, and of literally sitting at the feet of Andral, Chomel, Magendie, Roux, and Milne Edwards; whilst Rokitansky, Scoda, Liebig, and, later, Virchow, were raising the German School of Medical Philosophy out of its backward, or at least little known, condition, towards the pitch of eminence to which it has since attained. These men, he contended, were not only

intellectual giants, but they were scholars as well, and no doubt their scholarship was owing to the greater attention then paid to training in classical literature in the education of the physician than is the case now.

"And what was the condition of the provincial practitioner at this time? With the exception of a few local physicians of the older stamp, solemn, scholarly, and formal, and here and there an apothecary of more than ordinary acuteness of observation, there existed one dead level of mediocrity; men without the ambition to compete with their metropolitan brethren because the means of doing so were denied them."

Dr. Strange naturally attributed much of the improvements in the attainments and social position of members of the profession which have been brought about, to the working of the Association. "The aim of its founders was that knowledge should be freely and generously communicated by the free and generous intercourse between hitherto separated and scattered individuals. That this aim has fructified so as to justify its conception was, he thought, proved by the meeting he was addressing; by the vast numbers who now call the British Medical Association their professional parent; by their large and frequent gatherings for the promotion of social and scientific interests; by their current literature, and by the way in which it had forwarded those interests, and by the valuable and increasing efforts of research which the Association more and more supports and fosters. The influence of the *Lancet* also came in for notice, the President observing that the services which this remakable journal, after it had conquered its own independence, rendered to free medicine in the earlier days of its existence, amidst all its faults, failings, and even vices, were simply incalculable. Monopolies destroyed, hole and corner meetings, and doings of the corporations for the benefit of the few to the detriment and exclusion of the many, exposed, pompous ignorance and overbearing imbecility held up to scorn, the oppressed and obscure, but honest and industrious seeker after truth brought to the front. After a time, feeling its growing strength, this brave journal attacked the Legislature itself. And it was time. Its apathy towards all that concerned the interests of our profession, displayed in the tolerance of the most abominable abuses and monopolies in high places; its utter neglect of the public health, the farce of the Coroners' Courts, its winking at the atrocious adulterations of the people's food, its inhuman neglect of the sick poor, and its disregard of all decency in respect of the burial of the dead; these abuses were one by one attacked, and their authors and abettors lashed with a pitiless and unsparing hand, until redress and reform were grudgingly conceded." The good work done by the *Review* was also recognized.

In the second part of his address Dr. Strange said: "Looking upon the evolution of the medical mind as a continuous process, coming from whence we started, and going we know not whither, what are its characteristics at the present time? The first and noblest of them, I opine, is the love of liberty. Freedom to think, freedom to speak, freedom to write, freedom to teach. Fortunately for us, we have no thirty-nine articles to subscribe. We have no senate to revise and overrule the decision of the commonalty of medicine, no courts of appeal like our friends the lawers. Let us never relinquish into the hands of the State the decision as to what shall be the kind and amount of our knowledge on entering our profession, or in what way, and under what restrictions, we shall conduct our experiments and enquiries into the laws of nature for the good of mankind, or in what manner, and for what reward, we shall carry our knowledge to the bedsides of our patients, be they the rich in their mansions or the poor in our hospitals, or in what way we shall regulate our mutual intercourse. A second grand characteristic of modern medicine, I take leave to say, is philanthropy. By this term I do not mean to say merely that we are animated by the love of our species at large, by the common readiness to do good to our neighbor when opportunity presents itself, but that our profession is *ever* seeking out by toil of body and study of mind, *new* modes of relieving human pain and misery, that it ignores its own material advantage whenever that is placed in opposition to the good of our patients, or of our neighbors, and that it ever seeks to promulgate, against its own material interests, the doctrine 'that prevention is better than cure.'

"What remained to complete the Christian trial was truth—truth to Nature, truth to themselves, truth to their brethren, and to the world. If theories were pushed to an extravagant degree in order to bolster up some preconceived idea; if researches, which should be conducted only under the dry light of truth, were warped and strained to support a trembling reputation, truth must suffer." In this connection the President discountenanced the hasty publication, in the lay press, of so-called discoveries and improvements in practice, urging that, until the support of long-continued observation and experience was gained, publication should be restricted to the professional press. He also advocated the prosecution of knowledge by combined observation.

Then came a long report of the Council, and a discussion thereon. This part of the proceedings was quite as noisy and disorderly as usual. Dr. Milner Fothergill was to have moved a resolution in favor of having the editor of the Journal appointed for five years only, but for some reason best known to himself he kept away, and so the question is postponed till next year.

The question of the best means of excluding homœopaths came up for discussion, and it was wisely decided to rigidly prevent any of these irregular practitioners from entering the Association by any of its portals, but not to expel any who might have accidentally got in, and have been perverted to this heresy since admission. Following this was a noisy and excited discussion on a motion to introduce fresh blood into the Journal and Finance Committee, which is the real governing body of the whole Association, and which is reëlected year after year, and is consequently very conservative. The attempt was in great part successful.

This morning Dr. Wade, of Birmingham, delivered the Address on Medicine, of which this is an abstract:

Dr. Wade, in the course of his Address, gave a survey of the progress which had been made in the practice of medicine during the last fifty years. After showing the great advance which had been made upon the old theories, more especially with regard to bloodletting, which had been exploded, and the manner in which disease was now treated, he remarked that a dispassionate survey of present medical practice forced him to the conclusion that on a very large scale, and in both chronic disorder and organic disease the physiological basis of treatment was too often unduly subordinated to the restorative basis of treatment. He beseeched them to analyze each for himself, and in his own way, the conceptions and the practices of those who had gone before. The lessons he had been trying to enforce were no new ones; the doctrines they embodied had underlain the actions of all the great practitioners of the past. He ventured to think they ought to be assimilated by all practitioners in the future. The greater their advances in the science of anatomy, physiology, and pathology, the more need was there that their powers of observation should be sharpened, refined, and sensitized, for in the same proportion would new suggestions arise of modes in which this

knowledge might be transmuted into means of influencing the processes of disease. To each one was given to render the practice of medicine more rational, more common sense, because more truly scientific, to render more rare in the future such dark blots as they had regretfully recognized in the past.

At 1.30, five hundred members were entertained at luncheon by the Worcester and Hereford Branch of the Association, and the opportunity was taken to present a bust of Sir Charles Hastings to the Mayor and Corporation of Worcester. G. W. Hastings, Esq., M. P., gave some reminiscences of his father, which were very interesting, and although he had to tell of his many excellences, his great devotion to science and to duty, he skilfully avoided any mere eulogy. At 3 o'clock the Sections met. The number of Sections vary from year to year; this year we have eight, a full number. The President of each Section opened the proceedings with a short address. My space only allows me to speak very briefly of the Sectional work.

Dr. Clifford Allbutt, of Leeds, opened the *Medical Section* by an address on some of the more recent changes in medicine won, he asserted, by unity, and freedom of thought, chief of which he placed the discovery that force and matter are but one subject under two names. He then went on to point out the great importance of a deeper knowledge of the genesis of disease with a view to its prevention. Subsequently there was a discussion on the "systematic treatment of aggravated hysteria and allied forms of neurasthenic disease" opened by Dr. Playfair, who has been largely practising Dr. Weir Mitchell's rest-cure treatment.

For the *Surgical Section*, Mr. Pritchard, of Bristol, spoke of some of the changes in surgical practice during fifty years, and he particularly insisted on the value of counter-irritation by means of setons and issues, and of the median operation of lithotomy.

Mr. Greig Smith, of Bristol, read a paper on the *Early Treatment of Strumous Disease of Joints*. This, he stated, had two varieties—the one beginning as pulpy synovitis, the other as destructive inflammation of the joint marrow of articulated bone. For the former he advocated the free incision of the joint and the entire removal of all the pulpy tissue, to be followed by aseptic drainage of the joint. For the latter he recommended incision down to the bone, and removal by the gouge of all the inflamed bone. Both operations should be done with strict Listerian precautions. He asserted that, by these means, many cases of excision might be prevented, and recovery with perfect movement of the joints be secured.

Then followed a discussion on the *Treatment of Fracture of the Patella*, in which the Leeds surgeons (Wheelhouse, Teale, and Jessop) especially took part. The outcome was that for compound fracture, even when *very severe* and complicated, and for cases of useless joint from badly united fracture, suture of the fragments with strict aseptic precautions was the proper course to pursue, as it was not dangerous and gave excellent results in bony union.

Mr. Reginald Harrison showed the fragments of a phosphatic vesical calculus removed at one sitting by *litholapaxy*, weighing over two ounces. Mr. Gould showed a photograph of a stone removed by Dr. Bigelow in the same way which weighed over three ounces, and he mentioned a case recently under his own care in which he attempted to crush a stone weighing two and a half ounces, by Dr. Bigelow's new strong lithotrite, but failed owing to the inability of even this powerful instrument to crush it—he therefore had to cut the man, and he pointed out that there was therefore a limit to the cases in which lithotrity was practicable, The stone was an unusually hard uric acid one.

In the *Section of Public Medicine*, Dr. A. Carpenter referred to the work of the founders of the Association in this department, as recorded in the early volumes of the Transactions of the Association.

In the *Section of Anatomy and Physiology*, Prof. G. Humphry (Cambridge) opened by an address on the great value of the study of anatomy from an educational point of view, and then insisted that it should be combined with a study of the mechanics of the body, and the relations of the particular forms of structures to their special uses, and their most frequent injuries and diseases. Some rare abnormalities of the alimentary and genito-urinary organs were shown.

In the *Section on Pathology*, Dr. Hughlings Jackson (London) presided, and spoke of the great value of post-mortem examinations, and urged upon general practitioners the importance of losing no opportunity of witnessing them. In consequence of their infrequency in private practice, he suggested that the doctors of a district should associate and each give notice to the others when he was called upon to make an autopsy for the coroner or when he could have the presence of his fellows. A discussion on the *Pathology of Diabetes* followed, and specimens of minute changes in the cord and brain were shown under the microscope.

At six o'clock the Irish Medical Graduates dined together. In the evening a special service was held in the Cathedral, and Haydn's Creation was performed by the splendid choir. The fine building was crowded by a delighted audience. At the close a collection on behalf of the British Medical Benevolent Fund was taken.

Postscript.—Thursday, Aug. 9. At 8 A.M., about three hundred of us were entertained at breakfast by the National Temperance League, and appropriate addresses were delivered. To-day we have the Address in Surgery, further meetings of all the Sections, and the Annual Dinner in the evening. To-morrow the Sections meet in the morning, and then we all give ourselves up to amusements. But of all this I must write you next week.

PRESIDENT GARFIELD'S CASE.

To the Editor of The Medical News.

Sir: I beg leave briefly to call attention to some statements in the article of Dr. Baker, published in The News of July 29, which may mislead those of your readers who have not carefully looked into the matter, and which, had it not been for my unavoidable absence from town, I would have corrected at once.

1st. In describing the diagram of the Baltimore and Potomac Railway depot as having been "reduced from the copy used in the trial," he neglects to state that the dots indicating the positions of the President, the assassin, and some of the witnesses—the only points under discussion—were introduced by himself, or by some one, subsequent to the trial, and did not constitute part of the evidence. The diagram as published by him, and the theory of the shooting which he formed upon it, are, therefore, in no sense official. On the contrary, I am assured authoritatively that the prosecution was entirely convinced that the *first* was the fatal ball.

2d. The value of Dr. Baker's attempts to prove that the President turned to the right *after* the first shot was fired, depends altogether upon the truth of his assumption that the second shot was the fatal one. That this was not the case, is proven by the immediate evidence of serious injury given by the President after the first shot was received, and particularly by the fact, as to which there is no conflict of evidence, that after that shot, and while he was sinking to the floor, he threw

up his hands. Knowing this, it is easy to account for the wound upon the outer aspect of the left forearm, extending from the radio-humeral articulation for several inches in a direction parallel with the long axis of the radius, and corresponding exactly with the cut in the coat-sleeve. It is evident that this could only have been inflicted while the arm was raised, and, therefore, that it must have been caused by the second shot.

If any further evidence were needed in addition to these facts, and to the circumstance that the attending surgeons, with all the testimony obtainable immediately after the shooting, and the prosecuting attorneys with the additional information developed during the trial, were convinced that the first shot was the fatal one, such evidence may be obtained by reference to pages 121, 137, 151, 152, 169, 192, and 193 of the Official Report of the Trial of Guiteau. That any one could be willing, in the face of this testimony, and of the facts I have mentioned, to assert that "it is certain the second shot was the fatal one," is to me inexplicable. Dr. Baker's entire theory, together with his alleged ante-mortem diagnosis, and his criticism of the treatment, depends on his accuracy in regard to this point; it might have been supposed that he would exercise great care as to his premises before venturing to discuss the treatment of a patient he had never seen, and to differ with what he himself calls "the best surgical talent of the country."

Some minor inaccuracies may be mentioned as tending also to give rise to erroneous impressions regarding several interesting points.

3d. When Dr. Baker quoted the "general rule laid down by Hamilton, that conical balls usually go straight to their destination," he should have added that *rifle* balls were meant, and when he speaks of the "inadequacy of any soft tissue to stop a ball of forty-four calibre, fired with twenty-two grains of powder at six feet range," he should explain whether or not he regards two resilient ribs as in any way entering into the problem.

4th. Every surgeon who has had even moderate experience with gunshot wounds of the abdomen, knows how almost invariably vomiting occurs after such wounds, and would hesitate before asserting that on account of that symptom there had been "an injury to the solar plexus."

As to the internal hemorrhage, which Dr. Baker says was indicated by the "peculiar thready character of the pulse," and which he infers must have come from towards the spine, because "the vessels" lie there, the argument seems scarcely worth alluding to. It was impossible to say where the bleeding came from. It might have been an intercostal artery or some large muscular branch, as *all* the vessels do not "lie towards the spine," and at any rate, having ceased, it would have been contrary to all sound surgical practice to have disturbed the wound at the risk of renewing it. As to the removal of the small fragment of rib, any attempt to do this might have reopened a wound of an intercostal vessel, or have made one if it did not already exist, and have thus added a serious, possibly a fatal, complication to the case.

5th. Dr. Baker's statement of the elementary anatomy of the cœliac axis, the pancreas, and the splenic artery has no bearing on the interesting question as to the mode of production of the aneurism. The *fact* is that there were numbers of small granules of bone on the left side of the spine near the splenic artery, and that they were seen and spoken of at the time of the autopsy. Of course, they were perfectly competent to give rise to inflammation or other lesion of the artery.

6th. Neither have the cases quoted by Dr. Baker any relation whatever to that of President Garfield, or to my assertion that *perforating* gunshot wounds of bodies of vertebræ have invariably proved fatal. The writer, in the *Lancet* of May 27th, who after quoting Dr. Gaillard's case, added that it showed conclusively that "a gunshot wound of the body of a vertebra is not necessarily a fatal injury, as was hastily and unwarrantably stated in reference to President Garfield's case," committed a gross inaccuracy. Dr. Baker does not reiterate this absurd statement, but quotes it without comment, permitting the uninformed reader to suppose that it coincides with his views, although, of course, having studied the subject, he is aware of its essential falsity.

7th. As to several other assertions of Dr. Baker, the contradictory evidence is perfectly clear and conclusive. Dr. Lincoln was *not* with the President "most of the time on the day of the shooting," but only for a few minutes. The hyperæsthesia was *always* more severe in the right than in the left foot, and extended some distance up the leg, being far more intense upon the dorsal than upon the plantar surface; the tenderness did *not* extend from the scrotum over the lower abdominal region; the fracture of the rib *was* discovered at the first examination; the deflections of the ball before reaching the vertebra *were* confirmed by the official report of the autopsy; the testimony is *not* unanimous as to the directness of the second shot, nor does it, when read in its entirety, establish even a presumption in favor of any of the conclusions which Dr. Baker draws in reference to that shot.

8th. One or two opinions which he attributes to me in reference to the relative position of the wound of entrance and the fracture of the eleventh rib, and in regard to the enlargement of the wound and removal of the splinters, were certainly not contained in my paper. As in the question of the prognosis in perforating wounds of vertebræ, Dr. Baker might have spared himself some trouble if he had replied merely to what I did say, and had not supplied me with theories which neither I, nor as far as I know, any one else, ever believed in.

It seems to me, however, that "nothing could more strikingly illustrate the difficulty which physicians at a distance have in understanding this fatal case," than the difficulties which evidently surrounded those who had the advantage of living within a mile or two of the sick chamber.

I recognized so fully the impropriety of discussing a case with which I had no professional relation, that I did not venture to write upon the subject until I was assured that any errors arising from my want of personal acquaintance with the case would be corrected by my friend and teacher, Dr. Agnew; a similar supervision might perhaps have improved, though possibly somewhat shortened, Dr. Baker's excellent article.

Yours, very truly,

J. WILLIAM WHITE.

PHILADELPHIA, August 21, 1882.

RESUSCITATION OF THE DROWNED.

To the Editor of THE MEDICAL NEWS.

SIR: In your remarks upon the above subject, in the issue of THE MEDICAL NEWS of August 12th, you omit to mention a "method" which, in the experience of several physicians, has proven to be of much more value in the resuscitation of the drowned than any of those to which you allude. I refer to what I call the "speedy method" in asphyxia; and, as you seem willing to procure and to lay *facts* before the profession, I would respectfully call your attention to it, as it has been successfully applied in asphyxia of the neonatus in hundreds of instances within the past twelve years; and in that of drowned persons, in more than a

dozen cases, during the same period. You will find an article on "A Speedy Method in Asphyxia" in the January, 1880, issue of *The Independent Practitioner* (vol. i., No. 1, p. 11), published, at that time, in this city; and in the *Medical Record*, of New York, also. I feel confident that a perusal of the mode of practising it will satisfy you that it should be more generally known, and that it is *in no wise* inferior to *any* of the other known "methods!" It would, indeed, be an easy matter to find a large number of intelligent medical gentlemen here, and elsewhere, who regard it as *superior to any other* in the treatment of asphyxia of the neonatus; and all of those who have resorted to its use in cases of the drowned, regard it most favorably. I feel satisfied that your great interest in the profession, and in the preservation of human life, will cause you to give a knowledge of it the advantage of your large circulation, so that it may take the place to which it is entitled among the resources of those whose office it is to treat the asphyxiated.

I am, very respectfully, yours,

HARVEY L. BYRD, M. D.

127 N. ARLINGTON AVENUE, BALTIMORE, August 17, 1882.

INSOLUBILITY OF GELATINE CAPSULES.

To the Editor of THE MEDICAL NEWS.

SIR: The subjoined observations were made after free and indiscriminate use of the gelatine capsule, and corresponding facts may be attested by any careful, vigilant practitioner. A point of interest drawn from these notes is, that the cases in which the observations were made were those of young children and old persons, in both of which classes the digestive function is naturally feeble. The appearance of the capsules when ejected was that they had attracted the viscid mucus of the stomach by their natural adhesiveness, and being encased in this, had traversed, unscathed, the remainder of the alimentary tract.

It is not to be understood, however, in the opinion of the writer, that these are the only classes of patients in which the same objections to their use may be not unjustly urged. Individuals of all ages, sick with malarial fevers, in which the gastric and hepatic secretions are more or less suppressed, may fail to respond to remedies given in this way, for the same reasons which explain their inefficiency in the cases noted, although no facts are in my possession to make this statement other than inferential.

1st. No. 1 gelatine capsules containing sulph. quinia may be ejected from the stomach of a child four years old, sick with remittent fever, six hours after administration, the capsule and quinia both undissolved.

2d. No. 1 and No. 2 gelatine capsules containing calomel, Dover's powder, and pulv. rhei, may be discharged from the rectum of a child four years old thirty-two hours after administration, in remittent fevers, the capsules remaining *in situ* and powders undissolved.

3d. No. 3 gelatine capsules containing sulphate of quinia may be discharged from the rectum of a healthy child thirty-six hours after administration, the capsules being *in situ* and contents undissolved.

4th. Gelatine capsules containing various drugs may be discharged from the bowels of a woman fifty to sixty years old twenty-four hours after administration, neither capsules nor contents having been acted on by the gastro-intestinal secretions.

5th. Nos. 1 and 2 gelatine capsules, containing various drugs, may cause by their presence in the bowels of a child four to eight years old, sick with remittent fever, serious cerebral symptoms, to which the condition of the circulation indicates no claim.

The foregoing observations have been made with gelatine capsules manufactured by Parke, Davis & Co.

Respectfully yours,

R. T. BYRD, M.D.

BOLIGEE, ALA., July 28, 1882.

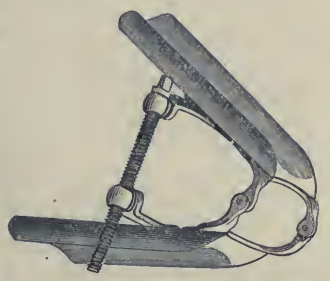
NEW INVENTIONS.

A NEW SPLINT TO REPLACE THE STROMEYER.

BY W. W. KEEN, M.D.,

SURGEON TO ST. MARY'S HOSPITAL, PHILADELPHIA, ETC.

THE Stromeyer splint can be completely extended, but if *flexion* be desired, it cannot be obtained, since the screw intervenes between the two arms of the splint. This is the first and chief inconvenience of the splint. Moreover, at the joint it very often causes excoriation of the skin by pressure.



Both of these evils are remedied by the form of splint figured above. To remedy the first evil, two metal plates are screwed to the wooden pieces, with lateral projections which carry the screw. The latter cannot then interfere with flexion. Either of the collars through which the screw passes can be made with a thread, and the other without it, if forced motion be desired in only one way. If forced motion in both ways be desired, the lower collar should be free from any thread, the end of the screw being flanged above and below the collar, while the upper collar should have a thread. Each collar is on a pivot, made needful by changes in the relative positions of the two wooden arms in varying degrees of flexion. If complete extension be required, the screw must be long enough to allow of it.

The second evil, pressure, is avoided by the arrangement at the joint. This is sufficiently plain in the engraving, without any further description. Nor is it needful to suggest the cases in which it may be used, as they will readily suggest themselves to any practical surgeon.

NEWS ITEMS.

WHEELING, WEST VIRGINIA.

(*From our Special Correspondent.*)

THE STATE BOARD OF HEALTH OF WEST VIRGINIA; ITS PROGRAMME OF SANITARY WORK.—Having completed the medical registration in conformity to law, the Board is now actively engaged in purely sanitary work. As a ready means of educating the people in sanitary matters, a "Health Primer" is to be published at a very early date—probably by October 1—and distributed broadcast over the State. Two subjects have been assigned each member of the Board for study and report. The following schedule will show the character and scope of the proposed work:

Hon. A. R. Barbee, M.D.—1. Stimulants and Narcotics. 2. Climate, Topography, and Geology.

Geo. H. Carpenter, M.D.—1. What to Eat and How to Cook. 2. The Duty of the Medical Profession.

Lawrence Carr, M.D.—1. How to Resuscitate the Drowned. 2. Diseases and Accidents of Coal Mines.

Wm. M. Late, M.D.—1. The Houses we Live in. 2. Our Domestic Animals and their Diseases.

Geo. B. Moffitt, M.D.—1. How to Nurse the Sick. 2. Drainage and Sewerage of Towns and Cities.

Gabriel McDonald, M.D.—1. Contagious and Infectious Diseases. 2. Country Life and its Exposures.

C. T. Richardson, M.D.—1. Accidents from Explosions and Poisons. 2. Health of Freedmen.

James E. Reeves, M.D.—1. Domiciliary Hygiene. 2. Hygiene of the School-room.

Papers "No. 1" will go into the "Health Primer." Papers "No. 2" are for the next annual report to the Governor, which the law requires shall be made on or before January 1.

VIENNA.

(*From our Special Correspondent.*)

Departure in Therapeutics—Grape Cure in the Volksgarten.—Dr. v. Hibentauz has succeeded in introducing into the Volksgarten an establishment having for its object the cure of numerous diseases through the agency of grapes, variously combined with tannic acid. Much discussion as to the merit of the undertaking is rife among medical circles. The institution will be opened towards the latter part of August, when the grapes begin to ripen.

Ovation to Prof. E. Ludwig.—Prof. Ludwig, who recently received from the Faculty of the University of Vienna the honorary degree of Doctor of Medicine, was tendered, within the last few days, an ovation at the hands of his students. The occasion was a highly enjoyable one, although the Professor's modesty made it a little painful for him, at first.

Dr. Mickulicz.—Dr. Mickulicz, first assistant of Billroth, and Docent of Surgery, has been named as a candidate for the Chair of Surgery vacant in Krakau. Dr. Rydygier, of Culm, who excised the pylorus for ulcer recently, is his most important rival.

Anniversary of the Founding of the University of Würzburg.—The students and authorities of the University of Würzburg will celebrate the three hundredth anniversary of the founding of that famous school, this week. The festivities will be of a very imposing character and will last five days.

Medical "Diploma" from the "University of Philadelphia."—D. Herzl, a dental technologist, was recently summoned to appear before a magistrate in the Inner City, Vienna, and was charged with having drawn teeth without necessary qualifications, and with having furnished the same individual with a set of false teeth, whose spiral spring was made of a composition of copper, nickel, and zinc, plated with gold. The patient deposed that the false teeth occasioned pain in her cheek, produced an unpleasant taste in her mouth, and were otherwise annoying. Medico-legal chemist, Prof. Ludwig, and dentist, Prof. Scheff, were present as experts. Both experts united in the opinion that the effect of the composition metal was in the highest degree injurious. Prof. Scheff stated that the accused was guilty of malpractice in the insertion of a set of false teeth two weeks after the former teeth had been extracted. Under such circumstances three months, at least, should intervene.

The Dental Technologist produced as one and his chief qualification a diploma in medicine from the "*University of Philadelphia.*"

He was found guilty, fined, and placed under arrest.

The Columbus (O.) Medical College.—Dr. J. T. Baldwin, lately Professor of Anatomy in the Columbia Medical College, in a signed letter to the Columbus *Sunday Morning News*, states that the Columbus Medical College graduated a man "who didn't know what the iris was, nor the pupil; could not locate the mitral nor tricuspid valves; placed the valvulæ conniventes in the *brain*, and the ileo-cæcal valve in the *rectum!*" He also says, "I have absolute proof of the graduation of one man who had never attended a previous course of lectures, and who made no claim to have done so;" and "I have been shown a letter, written by the Dean, in which he tells the person addressed that he can graduate by paying half the term fee, all the graduation fee, and passing an examination in Practice, Surgery, and Obstetrics, and that he need not come to lectures *until examination week.*"

Preliminary Examination at the University of Pennsylvania.—The University of Pennsylvania is arranging for the holding of admission examinations to its Medical Department in cities remote from Philadelphia, in order that students residing at a distance may not be discouraged from applying on account of what would seem a useless expense in coming to Philadelphia, in the event of their failure to pass the preliminary examination.

Canada Medical Association.—The next meeting of the Canada Medical Association will be held in Toronto, on the 6th, 7th, and 8th of September, under the Presidency of Dr. Fenwick.

The Italian Medical Congress.—The tenth Italian Medical Congress will be held in Modena early next September. It is expected that His Excellence, Dr. Bacelli, Minister of Public Instruction will be present. At the same time as the Congress, there will be held an Exhibition of Hygienic Appliances, and of objects generally connected with sanitary science.—*Brit. Med. Journ.*, Aug. 5, 1882.

International Congress of Hygiene.—At the meeting of this Congress to be held at Geneva, M. Pasteur will read a paper on the *Attenuation of Virus.*

University of Edinburgh.—At the annual conferring of degrees on August 1, the degrees of M. B. and C. M. were conferred on the largest number of graduates the Edinburgh University has ever sent forth. The degree of M.D. was conferred on thirty-two candidates, and the degrees of M. B. and C. M. on one hundred and eighty-one candidates.

The Philadelphia County Medical Society's Course of Lectures.—The Philadelphia County Medical Society has determined to institute an annual course of lectures on topics in medicine, surgery, and obstetrics, which shall be of general professional interest. The first annual course will be delivered during the ensuing winter by Professor Austin Flint, Sr., who has chosen for his subject, "Practical Points in the Physical Exploration of Visceral Diseases."

Meeting of the American Academy of Medicine.—At a recent meeting of the Council, it was determined to postpone the annual meeting of the Academy until Thursday, October 26th, when it will be held at Philadelphia, at the time of the Bicentennial Celebration in that city.

Cure of Diphtheria.—M. and Mme. St. Paul have offered to the French Academy the sum of 25,000 francs as a prize to be awarded to the person, without distinc-

tion as to nationality or profession, who shall discover an efficacious and sovereign remedy for diphtheria, the Academy deciding as to the merits of the claim. Until the discovery of this remedy, the interest of this sum is to be granted biennially by the Academy to those whose essays on diphtheria seem to deserve recompense. Six memoirs have already been presented, but were not deemed worthy of the prize.—*Gazette Méd. de Paris*, August 5, 1882.

Ross on the Nervous System.—In its review on Ross on "The Diseases of the Nervous System," the *Edinburgh Medical Journal* (July, 1882) shows where the author's ignorance of German, and his unfortunate habit of not giving credit for what he borrowed, lead him to make an amusing mistake. "The case of Sterne," he says, "who saw distinctly the satellites of Jupiter with the naked eyes, is a good example of optic hyperæsthesia" (p. 313, vol. i.). Sterne—there is only one Sterne—was a very clever and amusing fellow, but we never heard before of his sharp sight, and as he died in 1768, this is just a statement which ought to have a reference to confirm it. Unluckily for Ross, we have accidentally fallen upon this reference. Here it is: "Ich erinnere nur an die Beobachtungen, dass Sterne siebenter Grösse und die Jupiterstrabanten mit blossem Auge deutlich erkannt wurden" (I am reminded of the observation that stars of the seventh magnitude and the satellites of Jupiter can be seen with the naked eye).—Eulenburg, *Lehrbuch*, etc., S. 321. The fact is quite as remarkable as before, but it loses much of its interest with the loss of the personality, "Sterne" being not, like "David," a man's name, but only the German for "stars," "siebenter Grösse," of the seventh magnitude. Ross must have been sorely exercised in his mind with this "siebenter Grösse." What on earth decided him to cast it aside?

Literary Notes.—We hear that Princess Christian, of England, is translating into English Prof. Esmarch's work, *Erste Hülfe bei plotzlichen Unglücksfällen*.

The Dictionary of Medicine, about to be published by Messrs. Longmans, will be issued early in October. It will form a volume of 1800 pages and numbers more than 200 contributors.

Foster's Physiology has been translated into Italian by M. Lessona, of Milan.

Dr. J. W. Little has just published a work on the *Medical and Surgical Aspects of Genu Valgum*, which he gracefully dedicates "To Professor Gross, M.D., D.C.L., etc. etc., Father of Surgery in America, an enlightened and honorable example of all that is noble in our profession, and to his medical and surgical brethren, in grateful acknowledgment of their cordial reception of him when on a visit to the United States in 1878, this work is inscribed by the author."

Statistics of Medical Journalism.—According to Dr. A. Dureau, one of the librarians of the French Académie de Médecine, the number of medical journals published at stated intervals in Paris is 95, and in the colonies 52, total 147.

The German Confederation publishes 133 journals, Great Britain 69, Austria 54, Italy 51, Belgium 28, Spain 26, Russia 26, Holland 16, Switzerland 10, Sweden and Norway 9, Denmark 5, Portugal 4, Danubian Principalities 4, Turkey 2, Greece 1. Total for Europe 583.

In America 183 journals are published, in Asia 15, in Oceanica 2. Total for all countries, 785.

The number of journals founded since 1679 exceeds 2500.—*Revue de Thérapeutique*, August 1, 1882.

The Salmon-disease and its Lessons.—Prof. Huxley has published some observations on the epidemic known as the Salmon-disease in the *Proceedings of the Royal Society*. The disease, as is well known, is produced by the growth of a parasitic fungus, and Prof. Huxley looks upon it as a disease of the same order as ringworm in the human subject, as the muscardine of silkworms, and the potato-disease. This fungus, which belongs to the order *Saprolegnia*, finds a suitable nidus in the skin of that part of the body which is devoid of scales, and generally first attacks the top and sides of the head; thence it may extend widely over the scaly surface also, and deeply into the true skin, causing extensive ulceration and sloughing, so that "one vast open sore may cover the top of the head from the snout to the nape, and may extend over the gill-covers." Several points of general interest have come out in the course of the inquiry; one of these is, that the fungus does not attack the viscera, so that the flesh of the diseased fish is probably not injurious in any way; and it has been said, by those who have made the experiment, that the palate can detect no difference between it and the flesh of healthy fish. This applies probably only to the early stage; for when death—which is produced by exhaustion—is approaching, the flesh no doubt deteriorates in quality. Another interesting point is the manner in which the sloughing of the true skin is produced. The fungus at first attacks the cuticle, but, after it has taken root there, it sends processes (hyphæ) downwards into the true derma; these processes branch laterally in every direction, and gradually extend deeper and deeper. The tracks of these hyphæ are not accompanied by any obvious inflammation; but they are so closely set, that they mechanically interfere with the nutrition of the part, and so lead to sloughing. The third point to which we wish to draw attention is, that the fungus is essentially a saprophyte—*i. e.*, it ordinarily finds its nidus in dead animal or vegetable tissues, and is only occasionally a parasite upon living organisms. Every stream in the kingdom probably contains indefinite quantities of this and allied fungi, which grow readily on the bodies of dead flies and other insects. Prof. Huxley thus arrives at a conclusion with regard to this disease, analogous to that to which the student of human pathology is often brought in the case of many infectious diseases—namely, that, though the parasitic organism may be the determining cause of the train of symptoms which come under observation, there are other, and as yet unknown, circumstances, extrinsic or intrinsic to the infected animal, in the absence of which the parasite cannot develop.—*Brit. Med. Journal*, Aug. 5, 1882.

Perils of the Hot-air Bath.—The hot-air bath, in all its varieties of construction and arrangement, is a powerful agent for the disturbance of the circulatory system. The change effected may be good, or it may be bad, for the subject; but it can scarcely be inoperative. The heart's action is quickened; the tension of the blood-pressure is at first heightened, and then—if copious perspiration take place—it may be reduced. Speaking generally, there is a determination of the blood to the surface, leaving the central and deep organs less fully supplied than before. In this way, doubtless, local congestions are occasionally relieved by the bath. Under ordinary circumstances, the change effected in the distribution of blood and pressure is likely to be beneficial, but if the heart be weak, or the larger vessels rigid, it may happen that faintness ensues. Then something is done, either by the affusion of cold water on the extremities, or in one or more of several empirical ways, to drive the blood in again, and this endeavor may prove the last strain that throws the whole physico-vital apparatus of the circulation out of working order, and renders the continuance of the essential functions of life difficult or even impossi-

ble. We believe the Turkish bath to be a most potent and, when rightly managed, useful agent for the control of the circulation; but it is necessary to warn the public against the reckless use made of it in cases the precise nature and peril of which are not understood. Except by the robust and thoroughly healthy, the hot-air bath should on no account be employed without express medical approval. Even this restriction is scarcely enough, because it may happen that the subject of a weak heart or abnormal bloodvessels regards himself as healthy, until the unaccustomed demand made on his organs of circulation by the bath discovers the weak place in his economy. It is not desirable to lay too much stress on those deaths which occasionally occur in, or after a visit to, Turkish baths. They are accidents in the use of the agency, and as such must be regarded as significant. At the same time, it is desirable that the dangers of the bath should be more generally understood than they would seem to be, and that the proprietors of these establishments should be required to instruct their managers and attendants to send at once for medical assistance whenever a visitor becomes faint or even momentarily unconscious. Such occurrences must needs portend peril of death, and, however large may be the proportion of instances in which the "slight faint feeling" or "sleepiness" passes away, it is manifest that a grave risk is in *all* case incurred, and a responsible medical man should be instantly summoned to aid the recovery. There ought to be nothing left to the discretion of the manager or attendant in such a case. Again, although it is easy to see that proprietors would prefer to avoid deaths on their premises, no person who has been ill or even slightly unwell in the bath should be allowed to leave the establishment without being seen by a doctor. Further, we think the practice of *sleeping* in the hot rooms ought to be interdicted. There is always danger at the moment of awakening.—*Lancet*, July 22, 1882.

ANECDOTE OF NÉLATON.—Dr. Caradec gives, in the *Union Médicale*, July 2d, the following anecdote of Nélaton as authentic: A pet dog of the painter Meissonier one day broke one of his legs, rendered friable by over-feeding. Meissonier, desolated by such an accident to so beloved an animal, resolved to have recourse to the prince of surgical science, who at that time was Nélaton; but not venturing to declare the true motive, he telegraphed in hot haste for him as if to visit one of the family, then living at their charming residence at Bougival. Nélaton arrived, and entering the drawing-room, began talking on various topics with the master of the house, who, although he had painted many battles and carried off many victories, knew not how to face the present affair. At last Nélaton, becoming impatient at the delay, and knowing the value of his time, asked, to the great embarrassment of the painter, where the patient was. Presently the wounded brute was brought in on a magnificent cushion, howling with pain in spite of all the care taken. At so distressing a spectacle, Meissonier, forgetting everything else, exclaimed in agony, "Save him! illustrious master, save him!" Nélaton dressed the fracture, and the dog recovered; and shortly afterwards its master wrote a grateful letter to the great surgeon, thanking him for his kindness, and requesting to know his fee. Nélaton replied that when the painter came to Paris he could call upon him. This he soon did, and was producing his purse crammed with bank-notes, when Nélaton exclaimed, "Stop, sir! you are a painter, are you not? Just put a gray coating on these two panels which the cabinet-makers have finished!" This was indeed a delicate revenge; but which had the last word? Meissonier, who, going at once to work, at the end of a few days produced two of his *chefs-d'œvre* on the panels.—*Medical Times and Gazette*, July 22, 1882.

HEALTH IN MICHIGAN.—Reports to the State Board of Health, for the week ending August 12, 1882, indicate that bronchitis considerably increased, that consumption, neuralgia, tonsillitis, dysentery, and intermittent fever increased in area of prevalence. There was no marked decrease in any disease reported. Yet, compared with reports in preceding years, the sickness from intermittent fever, diarrhœa, dysentery, and typhoid fever, seems to be much less now than is usual at this time of year.

Including reports by regular observers and by others, diphtheria was reported present during the week ending August 12, and since, at 17 places, scarlet fever at 11 places, measles at 6 places, and small-pox at 14 places, as follows: In Walker Township, Kent Co., August 7; in Ionia Township, Ionia Co., near Carson City, in Westwood, Kalkaska Co., and at Custer, Antrim Co., August 10; at Detroit, Flint (2 new cases), Marquette (1 case), August 12; at Grand Rapids (4 cases), and Portland (1 new case), August 14; in Montrose Township, Genesee Co., August 15; in Danby Township, Orange and Sebewa, Ionia Co., August 16.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT, U. S. ARMY, FROM AUGUST 15 TO AUGUST 21, 1882.

MURRAY, ROBERT, *Colonel and Surgeon.*—Relieved from duty as Medical Director Military Division of the Missouri, and to report in person to the Commanding General Military Division of the Atlantic and Department of the East for duty as Medical Director of that division and department.—*S. O. 191, A. G. O., August 18, 1882.*

BILLINGS, JNO. S., *Major and Surgeon.*—By direction of the President, relieved from duty as a member of the National Board of Health.—*S. O. 190, A. G. O., August 17, 1882.*

HUBBARD, V. B., *Major and Surgeon.*—Now awaiting orders, to report in person to the Commanding General Department of the Missouri for assignment to duty.—*S. O. 186, A. G. O., August 11, 1882.*

SMART, CHAS., *Major and Surgeon.*—By direction of the President, detailed as a member of the National Board of Health, organized under Act approved March 3, 1879, *vice* Major Billings, Surgeon, relieved,—*S. O. 190, c. s., A. G. O.*

BYRNE, CHAS. B., *Captain and Assistant Surgeon.*—The leave of absence granted him in S. O. 68, July 12, 1882, Department of the South, is extended two months.—*S. O. 189, A. G. O., August 16, 1882.*

SENIG, B. G., *Captain and Assistant Surgeon.*—To be relieved from duty in Department of the Platte, and, on expiration of his leave of absence on Surgeon's certificate of disability, granted him in S. O. 121, c. s., A. G. O., to report by letter to the Surgeon-General.—*S. O. 186, c. s., A. G. O.*

TAYLOR, M. E., *Captain and Assistant Surgeon.*—Granted leave of absence for four months.—*S. O. 188, c. s., A. G. O.*

SPENCER, WM. G., *Captain and Assistant Surgeon.*—The leave of absence granted him in S. O. 80, April 7, 1882, from A. G. O., is extended two months.—*S. O. 191. c. s., A. G. O.*

ACUTE CATARRH OF THE MIDDLE EAR.

Two Lectures.

BY OREN D. POMEROY, M.D.,

SURGEON TO THE MANHATTAN EYE AND EAR HOSPITAL, NEW YORK.

LECTURE I.

GENTLEMEN: This affection is an inflammation of the drum cavity and Eustachian tube, of an essentially catarrhal nature. That is, it is of the milder order of inflammations of a mucous membrane, the products of the inflammation being only serum or mucus. The same inflammation intensified so as to produce a purulent discharge, is placed in the category of purulent inflammations.

Acute catarrh of the tympanum shows comparatively little tendency to destroy tissue, as is the case in the purulent disease, and as a result the membrana tympani is frequently not perforated, as is the rule in the other form. If the membrane is perforated, it is not likely to be the result of ulceration, which might produce a large opening, as in the purulent form, but rather of pressure from inflammatory products in the tympanum, and a fissure-like perforation, which rapidly heals, is likely to be the result. Inflammatory proliferation is much more likely to result than disorganization.

This affection is usually developed from some form of throat trouble, but may also depend on causes located externally. It may attack both ears simultaneously, but is more likely to attack the second ear, one or several days after the first. It may again attack one ear alone, but as the condition of the throat is usually at the bottom of the matter, sooner or later both ears are likely to be involved.

The attack generally comes on towards evening or in the night, the symptoms subsiding by morning, to recur again on the next evening unless interrupted by treatment. Its tendency to return whenever there is exposure to cold, or when the patient has been irregular in his habits, is well enough known. This is one of its most serious features, and often leaves the patient in a state of incurable deafness, unless great care is taken to treat symptoms promptly as they arise.

The subjective symptoms are about as follows: In a given case there may be a sore throat that has existed for a few hours or days, when a painful sensation is felt in one side of the throat, on which there may have been the greatest amount of trouble, which passes up the Eustachian tube towards the ear. After a little time the ear may have a full or stuffed feeling, which may be converted into a violent throbbing pain. The voice of the patient will sound hollow and out of pitch, the patient *feeling* it unpleasantly in the ear, for precisely the same reason that the tuning fork on the teeth is heard better in the ear affected with middle ear disease. Dr. Sexton, of New York, has called this symptom autophony.

The pain goes on, in a severe case, to a most intense degree, until secretion is inaugurated, or the membrane is perforated, when, with many premonitory loud crackling sounds, which may send sharp, darting pains through the ear, relief is experienced. I infer that the crackling sound depends on interchange of air between the throat and the tympanum. In very mild cases where there is scarcely any actual pain, this crackling is the most noticeable symptom of all. The Eustachian tube normally is nearly or quite closed in a state of quiesence, and by its valve-like faucial extremity resists to some extent the passage of air from the throat to the tympanum. When in a catarrhal condition, if the inflammation be not too intense there seems to be a relaxation of the tissue about the mouth of the tube, or the swelling of the lips of the tube prevents exact coaptation, and the consequence is that air is forced in or drawn out of the tympanum, causing this crackling sound. In other words, the tube is easily *forced*, and it will be found that Valsalva's operation is more readily performed than even in the normal state. Anything that condenses the air in the upper pharyngeal space will produce this symptom, as sneezing, coughing, blowing the nose, rapid expiration, especially if done through nostrils of narrowed calibre—which is likely to occur from the rhinitis so often accompanying this disease—eructations from the stomach, etc. When air is forced in with violence, much pain may be occasioned. On the other hand, rapid inspirations, especially if done through narrowed nostrils, rarefies the air in the upper pharynx, and air is forced from the tympanum into the throat.

When the auricle is pulled upon there is likely to be little or no pain, as the meatus and region about the concha are less frequently involved than in the severer forms of suppurative disease. Movements of the jaws, deglutition, sneezing, coughing, or talking, are often painful. If there are severe throat complications, the swallowing of cold water may cause exquisite pain. Movements of the head from side to side are often painful. There may be tenderness in the scalp, and pain in the side or back part of the head. Occasionally in the severer forms of the disease, there may be pain and tenderness in the mastoid region. The pain in the ear may extend forward to the teeth, and, indeed, may be more intense there than in the ear, just as in carious and painful teeth, the sensation may often be only in the ear. It is due to the fact that filaments of the fifth nerve are distributed both to the ear and teeth. In milder forms of the disease there may scarcely be any disagreeable symptoms except itching, deep in the meatus, which the patient often effects to relieve by scratching or thrusting his finger deeply into the ear, which frequently occasions throbbing and often results in much pain, with great aggravation of what were mild symptoms.

Sometimes the pain in the ear depends solely on the pressure of air upon the outer surface of the membrane the result of an insufficient pressure upon the opposite side. This is brought about by closure of the Eustachian tube, the consequences of the disease, the residual air in the tympanum soon becoming absorbed. There is great rarefaction of the air, amounting almost to a vacuum, and the membrane pushes the ossicles sharply inward, and the labyrinth waters are compressed by the settling of the base of the stapes into the oval window. I one time heard that Dr. T. G. Thomas was so interested in the result of an inflation of the tympanum in the person of his coachman, that he related the case before his class. The man had a mild form of tubal catarrh, which caused great pain. This was instantaneously relieved by Politzer's inflation. This pressure, incident to a collapsed membrana tympani, sometimes produces a feeling of fulness in the ear, difficult to diagnosticate from that of hyperæmia.

Deafness.—In the outset, before hyperæmia becomes excessive, and the parts are absolutely free from secretion, the ear being in a state in which irritation seems to predominate over inflammation, the hearing may be either morbidly acute, or sounds may seem to be heard with painful distinctness. Very soon a slight diminution of hearing is observed, or it becomes so profound that loudly spoken words cannot be distinguished. The deafness results from the following conditions: hyperæmia of the tympanum, producing pressure upon every portion of the contents of the tympanum, impeding the vibrations of the membrana and ossicula. This congestion may also extend to the labyrinth, and interfere with the function of the acousticus, for the time causing true nervous deafness, which may be recognized by the tuning fork.

Again, after the stage of secretion commences, the tympanum becomes more or less filled with the products of inflammation, which obstruct hearing by the retardation of vibrations. Naturally, filling the tympanum full, with bulging of the membrane, would produce profound deafness; but it has been found that a small amount of secretion may much retard hearing. I once removed one or two drops of serum from the tympanum by paracentesis and inflation, and the hearing was astonishingly improved. I believe that the smallest amount of mucus, resting on the round window, will interfere noticeably with the hearing, or any clogging of the movements of the base of the stapes by the same process will also much interrupt its function. Even if mucus smears the inner surface of the membrana tympani, and clings to the ossicles, there is interruption to free vibrations sufficient to cause deafness. There is another cause of deafness, more important than any I have mentioned—that is, the sinking of the membrana tympani, in consequence of closure of the Eustachian tube. In consequence of this collapse, the membrana tympani is put upon the stretch, the ossicles are crowded together, the base of the stirrup is driven into the oval window, the labyrinth waters are pressed upon, and the membrane of the round window may be pressed towards the tympanum.

Here are two causes of deafness, first, the interference of free vibrations of the apparatus of the middle ear by this pressure, and second, actual pressure upon the labyrinth. Whether this latter acts by pressure directly upon the nerve of hearing, or by the interference to the conveying of the sonorous undulations incident to increased pressure upon the labyrinth waters, it is hard to say. In my observations on the tuning fork and bone conduction, it will be seen that I incline mainly to the opinion that interference in the vibrations of the middle ear mechanism, is the principal factor in the causation of the deafness. The deafness generally comes on suddenly, the patient describing the ear as having suddenly closed up.

From the conditions just described, we have certain extremely disagreeable symptoms, namely, tinnitus aurium, hearing one's own voice too distinctly, which may also have a hollow reverberating sound, a stuffed feeling, or a feeling as though the ear was filled with some foreign substance. The latter symptoms may point indifferently to engorgement of the tympanum or a sunken membrana tympani. Another symptom dependent on pressure is vertigo. It may be so great that the patient has fears of falling out of bed.

Frequently, there may be no fever, and again, there may be a violent febrile movement. Sometimes delirium may be noticed, especially in young children. Many of the symptoms may simulate brain trouble.

Subjective symptoms.—In the first instance, there is likely to be signs of catarrh of the pharynx, with or without pharyngeal or laryngeal symptoms. The upper pharyngeal space is the one to critically examine; for the description of which, see naso-pharyngeal conditions giving rise to ear trouble. Naturally the rhinoscope will be needed here, and other instruments for examining the Eustachian tube. Externally, the meatus may show few signs of disease, except being reddened perhaps, and scruffy. The speculum auris may elicit some tenderness.

The membrana tympani is the important point of observation. It is true there may be a catarrh of the tympanum, without redness of the membrana tympani, provided it be sufficiently mild, but the membrane may show undue brightness of the light spot, from opacity of the mucous layer; hence, the augmented reflection at the umbo. Besides, the membrana tympani will not present the normal pearly-gray translucency, but will look flat or opaque, and of a darkish hue. Where the membrana tympani has become sunken, there will be the following changes: The malleus handle will be too vertical, or too horizontal; it may be drawn inward, giving it a *fore-shortened* appearance, it not appearing to approach to the centre of the membrane, but at a point upward, and generally backward. In consequence of this movement, the short process will be thrown outward, appearing too prominent. The light spot when present, will usually be too small; a better diagnostic, however, is a malposition of the reflex; it will present an acute angle with the anterior border of the malleus handle, or its angle may be too obtuse; it may be too near the centre of the membrana tympani, or be displaced towards the periphery. The folds of the membrana tympani may become greatly exaggerated, especially the anterior fold. The membrane may, sometimes, not be reddened at all. Again, where the mucous layer is intensely reddened, the membrana tympani will be more opaque, and when it still retains some translucency in its outer layers, this color may shine through as a faint dusky red.

The whole membrane may be congested so as to be completely reddened, but not of the intense red color described in suppurative otitis. More likely, however, the redness may be seen about the short process; after a little, a streak of redness may be seen coursing down the malleus handle, from congestion of the manubrial plexus of vessels. With a greater degree of hyperæmia, vessels may be seen shooting from the periphery to join those of the manubrium, when the whole of the membrane may become reddened. It is quite easy to discern individual vessels. Be careful to discriminate between the hyperæmia which is the result of disease, and that which is a consequence of traumatism. Rough handling of the ear in fixing the speculum or violent inflation of the ear will cause considerable redness of the membrane. If a number of persons examine an ear with a pretty hot artificial light, some congestion probably will result; where collection exists in the tympanum, the membrana tympani may bulge; if so, it will be generally found in the posterior superior quadratus and will seem to merge into the meatus; occasionally it may bulge in front as well, and the manubrium will seem to divide the membrane into two portions. If there is not too much congestion, and the outer layer is intact, a light reflex may be seen on the summit of the ectasia.

Again, if there is a collection in the tympanum with no change in the position of the membrana tympani, the light spot being against an opaque fluid will appear excessively bright and even glassy. I have often diagnosticated fluid in the tympanum by this symptom alone. If the subject is not too old with an excessively opaque membrana tympani the fluid may be *seen* through the membrane. It will give the latter a darker hue, perhaps of a yellowish or greenish cast. If there is considerable mobility of the fluid, its level may be changed by tilting the head forward or backward, or

cause it to disappear altogether by turning the head sharply to the opposite side. If inflation is done, the level of the fluid is changed, and often air bubbles may be seen about the top of the fluid, which are somewhat conspicuous.

By the use of Seigle's otoscope a hint may be gained as to the presence of fluid in the tympanum. If the membrana tympani is pushed sharply in, the fluid will rise, or it will recede if the opposite movement is made. The malleus handle fails to make the normal lever-like movement when any considerable collection is present. In rare cases it may be possible to assert that the contents of the tympanum is mucus or blood, by its color, but none but those very expert can determine this. Sometimes the fact of fluid in the tympanum may be elicited by auscultation with the diagnosis tube, a moist rattle or click is heard instead of a dry one, and the bursting of air bubbles in the tympanic fluid will yield a peculiar crepitating râle, which much practice will enable the surgeon to distinguish.

The diagnosis of acute catarrh of the tympanum is sometimes difficult. Very great pain with speedy rupture of the membrana tympani, and a purulent discharge proves that we have the suppurative form. In the mild cases where there is little or no redness of the membrana tympani, with the presence possibly of carious teeth, there will be real difficulty in determining whether the trouble comes from the ear or the teeth; sometimes it will be both. The use of the tuning fork, testing the hearing by other means, and contrasting the amount of hearing before and after inflation, making careful observation as to the presence of fluid in the tympanum, etc., will settle the diagnosis. Where there has been an old catarrh with impairment of the hearing, but which is improved by inflation, it is very difficult to tell whether it is the teeth or the ear which causes the disturbance. I have before now been in doubt, and have caused the teeth to be attended to, and the pain has disappeared. The pain from the ear is often of a neuralgic character, and may be indifferently in the head or ear, and will sometimes mislead us. In such cases it may be found that the pain does not follow the laws of a neuralgia, and some disturbance in the function of the ear may be noted.

In the adult there need be no trouble about mistaking brain symptoms for ear symptoms. In children there is much greater difficulty in diagnosis on account of absence of rational signs. I have, in the person of my own children, made this observation. The child would be restless most of a night, and no cause could be assigned for the trouble, when in the morning a discharge from the ear revealed the correct explanation. I think we are too loth to examine carefully the membranæ of children. In a case of considerable pain in a young subject, naturally we look to the bowels or head, or possible the teeth for the explanation, but if we always have in our mind a suspicion that it may be the ear which causes it, we shall be sufficiently on our guard. In a suspected case, if we do not too much object to do it, a hint may be gained by smelling the ear, when, by its peculiar odor, attention is at once directed to a diseased condition, if there be the slightest discharge. A little harsh handling of the ear may elicit tenderness, pointing to disease. If the patient has throat trouble of any kind, or has present the conditions which may give rise to ear trouble, we are put upon our guard. A little sufferer from ear pain, may reach the hand to the head and indicate the location of the trouble.

In the pneumonia of children, ear complications frequently arise which will give us a hint to inspect the ear when necessary. In examining a suspected ear in a child, even though we find no redness, we find great retraction of the malleus handle, which in children is a more conspicuous symptom than in the adult, and if it is very horizontal, and the opposite ear is normal, we suspect ear trouble. We inflate by Politzer, and the membrana tympani is restored to a more normal position, and the patient may be relieved from suffering, when the diagnosis is pretty well settled. Other means for the relief of pain in the ear may be used, and if they succeed, the fact points to the probability of ear trouble as the cause of the pain.

The causes of acute catarrh of the tympanum are so similar to those of the purulent form that I hardly need go into detail.

The first important factor in the pathogenesis is the inflamed throat. This may be excited by any catarrhal influence whatever.

The exanthemata are always liable to result in ear trouble consequent on the throat complication. Croup and diphtheria produce conditions in the throat liable to cause ear involvement. Some fevers may be accompanied by throat symptoms which sometimes result in ear complications.

Pneumonia and pleurisy are often accompanied by acute ear troubles, which depend, first, on the accompanying throat disease, and second, upon the violent interchange of air between the throat and ear, consequent on the rapid respiration incident to these diseases. This has been already explained. Besides producing labyrinth trouble, syphilis may, by its somewhat constant throat symptom, develop middle ear disease, without necessarily going deeper. Bright's disease, through defective blood vessels, may result in middle ear trouble; but, hemorrhagic disease through rupture of the vessels is more likely to occur. Whooping cough, by violent inflation of the ear during a paroxysm of coughing, sometimes ruptures the membrana tympani; but the violent inflation itself is sufficient to excite inflammation. Politzer's inflation may sometimes excite a catarrh of the tympanum. Tuberculous patients are strongly inclined to catarrh of the tympanum, in consequence of the extension of some form of bronchial or naso-pharyngeal catarrh, to which they are so subject, to the ear. Tuberculous matter (a cheesy material), in the tympanum, often results in middle ear catarrh.

Sea bathing, as in the case of suppurative trouble, excites this affection in several ways. Breakers striking the ear may rupture the membrane, or even if not ruptured, the cold water enters the meatus, which is enough to excite inflammation. Again, the patient may take the water into the mouth, and in the agitation and excitement, he may attempt imperfectly to swallow it, by which means some of it is forced into the tympanum and excites trouble. Sometimes, in swimming, a wave dashes the water into the nostrils, which, in the strangling efforts to remove it, is often forced into the ears. The nasal douche has inflicted many aural catarrhs upon those who use it, and I have abandoned it altogether. Even snuffing up water into the nostrils from the palm of the hand, has been known to pass into the ears and do harm. In my own practice of sending a few drops of salt and water into the nostrils by means of an atropia-dropper, it has occasionally passed into the ears, with deleterious effects.

The irritation of carious teeth, or even the advent of the wisdom tooth, has been known to excite an otitis. Teething in children has long been asserted to be a cause of otitis, and I do not doubt that it is — less frequently, however, than it is asserted to be. The cold pack in water cures, or the Turkish and Russian baths, have been known to excite this disease. As aural catarrh is more prevalent in the spring and fall, when the air is changeable, we easily infer that catarrhal influences are at work. Exposing the ear to a draft of air in any manner may provoke a catarrhal

attack. Taking cold, even though it be very slight, may, in those so predisposed, go to the ear. Another fact is of great interest, that the patient is much more likely to "take cold" when depressed, from any cause whatever, it apparently requiring a constant exhibition of vital energy to resist the inclement weather of our latitude. Many patients require cotton in the ears during the winter to keep them from becoming inflamed and painful.

ORIGINAL ARTICLES.

WHY SEWER TRAPS ARE UNRELIABLE, AND HOW TO APPLY THE OUNCE OF PREVENTION AGAINST DISEASE GERMS IN SEWER AIR.

BY JOSEPH G. RICHARDSON, M.D.,
PROFESSOR OF HYGIENE AND DEMONSTRATOR OF HISTOLOGY IN THE UNIVERSITY OF PENNSYLVANIA, PHILA.

THE practical bearings of this paper upon the life and health of 50,000,000 of human beings exposed here and in Europe to emanations from sewage are, it seems to me, so vitally important that I propose to commence by giving its salient points so closely condensed that they may be glanced over by the busiest reader. In the following pages, then, I assert—

1st. That, according to the germ theory of disease in the form for which during the past fifteen years I have been an earnest advocate,[1] diphtheria, typhoid fever, scarlet fever, and probably other contagious diseases, are connected with, if not solely due to, the development of spores or germs of vegetable organisms in the human body.

2d. That these germs propagate in sewers and float to us on the sewer air, penetrating into our dwellings through water closets, sinks, stationary wash-stands, etc.

3d. I have just discovered that the reason our various ingenious traps fail to protect us against these fatal sewer diseases is that sometimes a layer of micrococcus and mycelium creeps along the interior of the contrivance until it forms a new depot of development in the slimy vegetable lining extended into the *inner* or *house side* of the trap, from which, without obstruction, its deadly germs may be given off into the very bed-chambers of its victims; therefore,

4th. The true method of obviating this danger is by sterilizing with slow currents or drippings of solutions of sulphate of iron, corrosive sublimate, arsenic, carbolic acid, etc., the whole interior of our waste pipes, just as the shores of the Dead Sea and the banks of certain small streams are sterilized by mineral ingredients, or poisonous metallic substances from manufacturing refuse, with which their waters are mingled.

The first proposition above enunciated needs no defence with believers in "organic entities" as causes of disease, and to the conservative majority of our profession who still doubt the germ theory, I would urge that sanitary precaution in accordance with its doctrines is now an imperative duty, since this hypothesis has been accepted by such a respectable minority of physicians, including a large proportion of those whose special studies of medical microscopy have best qualified them to judge its merits. Only a duty, I admit, however, as yet, *provided* these precautions do not themselves involve danger to health; do not interfere with other safeguards dictated by rival theories of disease; and are not so troublesome as to be practically inapplicable.

I cannot claim in support of my second proposition that I have ever yet propagated any of the disease poisons in a sewer, and yet the innumerable culture experiments of Koch, Klein, Pasteur, H. C. Wood, and a host of their disciples, have so conclusively shown that the conditions of algoid growth are warmth, air, moisture, and nitrogenous matter, that I think there can be no reasonable doubt that propagation of disease germs does frequently occur in sewers, where it is incontestable that these necessary physical conditions are *all* abundantly present. I have determined by direct observations upon the gelatinous films of vegetable growth lining waste-pipes communicating with sewers, the presence of micrococcus, bacteria, and mycelium, morphologically identical with those of diphtheria, and of Klein's pig-typhoid fever; and since the condition of existence for the common forms of these low vegetable organisms and for the disease germs are known to be similar, it becomes, I think, certain that in situations where I found abundant algoid spores and mycelium, the disease germs of diphtheria, typhoid fever, etc., could have propagated themselves had they happened to find a lodgement. Lastly, as direct evidence from the clinical side of the question, we have such suggestive records as the following "stubborn facts:" Dr. Wm. N. Thursfield, of Birmingham, England, reports tracing an isolated case of diphtheria to temporary exposure to "sewer gas" in a house on a short line of sewer which he *knew* to be specifically contaminated by diphtheria. This sewer, when opened and examined by a surveyor, produced in him a severe diphtheritic attack (*London Lancet*, August, 1878, p. 211). Dr. Wm. V. Keating details at length four cases of typhoid fever attributed to sewer gas from untrapped drain pipes, and refers (on page 117) to cases of measles, scarlet fever, and diphtheria in two other families apparently from the same cause (Trans. of College of Physicians of Philadelphia, 1879, p. 85). Dr. C. W. Chamberlin, of Hartford, relates a remarkable case of fatal erysipelas seemingly due to sewer gas from a waste pipe carelessly left open beneath the bed of the patient (Connecticut State Board of Health Report for 1880, p. 5). Dr. Geo. Wilson quotes the account of 20 out of 22 boys at Clapham, England, in 1829, who were attacked with violent vomiting, purging, and fever within three hours after standing over a choked-up drain, watching the workmen clean it out (Wilson's Handbook of Hygiene, 3d American edition, p. 68). Nor are these isolated instances, for the medical journals of America and Europe record numerous

[1] See Experiments showing the occurrence of Vegetable Organisms in Human Blood.—Amer. Journ. of Med. Sciences, July, 1868, p. 291. Handbook of Medical Microscopy, Philadelphia, 1871, pp. 196, 252. The Germ Theory of Disease and its present bearing on Public and Personal Hygiene.—Penn Monthly, Nov. 1878, p. 858.

similar examples of dangerous or fatal effects from disease poisons in sewer air when inhaled by human beings.

The most important fact mentioned in my third statement was discovered in a purely accidental manner, as follows:

On moving into a new residence I had all the stationary washstands fitted with ball-traps of the most approved construction. Noticing, however, after a few months, that the flow of waste water through one of them seemed to be impeded, I unscrewed the glass cup which forms the lower segment of the trap for the purpose of removing the obstruction, and was surprised to find what appeared to be a fragment of thick black blotting paper hanging from the vertical pipe. On further investigation I discovered that this was part of a continuous lining to the upright tube of the trap, which lining extended a little above the ordinary water level on the inner or house side, and in order to determine its nature I detached a portion for microscopical examination. At first I did not appreciate the tremendous importance of my observation, but on finding, under a power of 1250 diameters, that the film was a felted mass of mycelium, bacteria, and micrococcus, I realized at once that the existence of such a lining of vegetable growth completely through the trap from its outer to its inner limit accounted for the penetration of disease germs through the best of these contrivances, and explained that frequent and deadly entrance of sewer infection through apparently tight traps which has been the despair of plumbers, sanitary engineers, and hygienists. Manifestly if the bacteria of putrefactive decomposition which make up this filthy coating, called *seilhaut* by the Germans, and probably in their growth give off the disgusting odor popularly known as "sewer gas," could thus intrude to the house side of the trap across the microscopic inequalities of the surface to which the ball "fitted air-tight," the micrococcus of diphtheria could likewise penetrate by the same occult but infallible pathway, and only chance had saved me and my family from similar access of typhoid fever or other pestilential germs. And it is further obvious that the various theories to account for sewer infection in spite of air-tight traps, such as the siphoning out of traps, their partial corrosion and leakage, the absorption of sewer gas by the fluid sealing them, and its evolution from the inner or house surface, etc., may be relinquished.

Fourth, as a remedy for offensive sewer emanations, solution of sulphate of iron (common copperas) has long been known, and I am strongly inclined to hope that in it, when *properly and systematically applied*, we have an agent capable of making the surface of waste pipes unfit for vegetable growth or life, and so rendering these conduits completely sterile, just as certain weeds may be killed and conquered by watering the ground where they grow with a strong saline solution. American inventive genius will probably supply a variety of contrivances for applying suitable parasiticides for this purpose as soon as any demand for them shall arise, but in the mean time I would suggest the use of the following simple apparatus which has proved quite successful in my own residence. Fit a half-gallon bottle with a tight, perforated cork carrying a glass tube about three-sixteenths of an inch in diameter; fill the bottle with solution of copperas of the strength of one ounce to the pint of water, adapt the cork and invert the bottle over the basin (for example) of a stationary washstand, so that the fluid may slowly drip down the waste pipe. The apparatus may be conveniently supported on a board laid across the basin, and having near its centre a two-inch hole into which the neck of the inverted bottle is inserted. A pint or so of the same solution should first be poured down the holes of the overflow pipe, and the best time to use the contrivance is on going to bed, so as to leave the trap full over night of the mineral solution. Application in this way twice a week has so far seemed to answer the purpose in my house, but a still more effectual method would be to have a stop-cock placed in the waste pipe a foot or two below the trap, and every night or two closing this, fill the former and the adjacent portions of pipe with copperas solution.

I believe we will only effectually combat these multitudinous disease germs, when we fully realize that they are each struggling to live and reproduce their kind, just as are the higher plants and animals throughout the whole course of Nature.

The fact that thistles and other noxious weeds so soon appear in neglected fields or gardens, shows beyond dispute how widely, and yet how imperceptibly, their seeds are disseminated, and how eager these seeds are to seize every chance for reproducing themselves after their kind, whenever and wherever suitable warmth, air, moisture, and nourishment happen to be afforded them. Even a little handful of earth in a rocky crevice is often forced to support some wandering nettle or poison-ivy, and its progeny of organisms hurtful to man, perhaps through a long series of generations.

In like manner, apparently, every diphtheritic spore and typhoid fever germ strives with all its puny might to live and grow and multiply itself, in the blind hope, as it were, that one of its iniquitous progeny will succeed in fastening upon some human being, whose affirmative power of constitution (as Emerson so aptly called the Life Force) is feebler than its own, and so accomplish its malevolent destiny. And whilst millions of such germs die for want of moisture, warmth, air and nitrogenous matter, and hundreds of millions flourish uselessly, because they cannot gain access to mankind, a few (relatively) out of these vast numbers steal past air-tight traps in the manner I have pointed out, and, establishing themselves on the inner side of such "safeguards," may be reproduced luxuriantly, and, under favorable circumstances, succeed in sending some of their descendants to inflict upon us the well-known disturbances of health which characterize the different contagious diseases.

Varied and prolonged courses of experimental inquiry will doubtless be requisite for deciding numerous minor details, and especially just how often waste-water pipes must be bathed with solutions of mineral substances, in order to secure the desiderata

above indicated. But I am confident that the key to this momentous problem, of how to avoid infection from "sewer gas," or, more correctly, sewer air, entering our dwellings, is to be found in the principle of *so sterilizing* the whole interior of all pipes communicating with sewers, and, if possible, of the sewers themselves (by frequently irrigating them with fluids containing metallic compounds *poisonous* to plant life), that no vegetable organisms can propagate within them. Under such circumstances, *disease germs*, even if they penetrate for short distances through imperfect traps, will be powerless for evil, because a noxious element being introduced into their environment, the harmoniously favorable conditions necessary for their development and reproduction are disturbed.

HYPODERMIC INJECTION OF COLD WATER FOR THE RELIEF OF PAIN.

BY S. J. RADCLIFFE, M.D.,
OF WASHINGTON, D. C.

CASE.—I was called about 6 P.M., October 22, 1881, to see Mrs. B., aged 35 years, short in stature, stout, round in figure, mother of four children, youngest 4 years of age, nervo-sanguineous temperament, looking in perfect health.

She said she had rarely been sick; had indeed always enjoyed good health. Her husband informed me she had had, some years previously, attacks of hysteria, and it always seemed to be associated with symptoms of malaria. I treated her in May, 1881, for a sharp attack of acute bronchitis with bloody expectoration, lasting some two or three weeks, from which she recovered well.

She said she was suffering from exceedingly severe neuralgic pains about the waist, stomach, and under the right breast, following a chill which occurred about noon that day. She said she thought she had been suffering from malaria for some time, for which she had been taking quinia almost daily, but in spite of the quinia the malaria had culminated in the chill and fever, leaving her with the terrible pain for which she now sought advice.

She was in bed covered up in blankets and bedclothes. Her pulse was regular, a little accelerated, respiration hurried, temperature normal, some moisture of surface. She said her bowels were regular, her uterine function normal, her appetite fair, and she usually slept well. There was no evidence of debility or anæmia. Digestion and assimilation were perfect; she was well nourished. The only history of malaria was that given above.

Physical examination revealed no enlargement of spleen, no trouble of heart or lungs; there was no tenderness on pressure over the side or abdominal region. There was neither headache nor other cerebral symptom. The pain in the side and breast was the only symptom of which she complained, and she described it as of the severest character, impeding respiration and causing her to gasp for breath, and surpassing any pain she had ever had.

I injected ⅓ grain morphia sulphate hypodermically in her right arm, on the side of the pain, and directed her to continue the quinia and also to take 20 grains potassium bromide three times daily, beginning the next morning.

On the 23d she was better. The morphia relieved her, she had slept comfortably all night, and felt no symptoms of chill and had no pain.

She had no paroxysm and was free from pain on the 24th, and also on the 25th, and she was ordered to continue the quinia and bromide as directed.

On the 26th, three days after the last seizure, on the fourth day, she had another paroxysm, equally severe, she said, as the first, preceded by the chill, accompanied by the same symptoms, and ending in the same lancinating pains—the pain occurring about the same hour of the day.

Her condition when I saw her was just the same as at my first visit. The fever had subsided, the pulse and temperature were but a little above normal, the respiration was a little hurried, the surface was somewhat moist. There was no indication of any great abnormal condition or constitutional disturbance, except the pain, which was the principal feature in the case.

I injected again, hypodermically, ⅓ grain of morphia sulphate in the right arm, and directed her to continue the quinia, 10 grains each morning, and the bromide three times daily, as previously ordered. She had no paroxysm on the 27th, nor on the 28th, but had one on the 29th and one on the 31st, under the same circumstances and conditions —having the chill at noon, then the fever and the sweating, she said, and then the same excruciating pain—the apyrexias being three days, except the last, which was but two. I injected as before in the arm, ⅓ grain of morphia at each visit, continuing the same directions as previously given, except to take an additional dose of 10 grains of quinia at bed-time, making 20 grains daily.

She had another paroxysm November 1st, and another on the 2d, and one on the 3d, about the same time of day each day, the last phase of it, the pain, about 6 P.M., as before, at which time I was usually sent for, and I found her always at each visit under like conditions, and begging for relief from the awful pains, which she said were increasing in severity rather than diminishing.

I gave her at each visit ⅓ grain of sulphate of morphia hypodermically, with the same relief from pain, and the same gratification to her as before—directing the same treatment to be continued as already given. She had no paroxysm, and was free from pain or other disturbance until the 7th, when she had an attack equally as severe as any previous one. She seemed, indeed, to be more hopeless and despondent than ever.

I determined now to abandon all former treatment, especially the morphia, for which I found there was a growing desire, which might lead to the opium habit, and resort to what I might almost call a *placebo*, in the form of hypodermic injections of cold water. I consequently injected 15 drops of cold water in her right arm as I had done before with the morphia. I was surprised to find it relieved the pain quite as well and as promptly as the morphia. All other treatment was now discontinued.

She was well and free from pain on the 8th, 9th,

and 10th, but had another paroxysm on the 11th, milder in type, four days having elapsed since the last, and her condition was very materially improved. I injected again, 15 drops of cold water in the right arm, as I had previously done, which again entirely relieved her of pain, and she remained well and comfortable until the 15th, again four days (the fifth day) since the last paroxysm. Under the cold-water treatment the paroxysm had been delayed until the fifth day—changed from paroxysms occurring daily, and they were neither so intense nor continuous, and the intervals were spent with more satisfaction and freedom from anxiety.

Anxious now to try the comparative value of minute doses of morphia with the cold water, I injected 5 drops of Magendie's solution, observing the same rules as with a larger dose and with the water. I found its action was hardly adequate to relieve the pain, and its effects were only manifest after a considerably more protracted period. In consequence, the next apyrexia was only twenty-four hours. She had another paroxysm on the 16th, and went through the same ordeal as before, the pain, she said, being quite as severe as any previously endured.

I injected now fifteen drops of cold water hypodermically in her right arm as before. The relief of pain was as prompt and complete as in the previous instances, and it was as wonderful as singular to see with what success it acted. Her complaints seemed to quiet or cease in a very short period, and her pains fled with her complaints.

I saw her at short intervals until the 5th of December, twenty days after the last paroxysm, and the same time after the last injection of cold water. She had received no treatment in the mean time, had remained well during that period, and her general appearance was especially good in every particular. Her sickness had left no deteriorating marks, she had not materially lost in flesh, and she stated she could attend to her household duties and take long walks without fatigue, and was not cognizant of any more debility, but felt quite as fresh as before her first attack, and, realizing her improved condition, she said she was preparing to take a long journey to the far West, where she hoped to escape all malarial influences.

Remarks.—It will probably be admitted by all that physicians are called to treat cases where the diagnosis is not always easily made, and the line of treatment is not always apparent. In other words, they find many patients whose disorders are simulated, not always with the view to deception, indeed, but in many cases because of a want of a proper knowledge or appreciation of their condition, and who assume causes and effects with regard to themselves, which are not only not rational, but often lead to error, especially where reliance is placed on the objective symptoms alone, which, however, are in no wise unworthy of notice, and in many cases give all the information we can obtain.

It is in these cases of simulated or pretended diseases that the practitioner is often thrown off his guard, particularly when the patients are persistent in their explanation and view of the case, and strenuously insist that they really suffer from the diseases for which they seek advice; and it is only by an independent and firm course that the proper remedies can be applied to counteract the mental, as associated with the physical, malady or condition of the patient.

The majority of these cases are of the better class of society, live well or even luxuriously, seem to enjoy perfect health, appear to have no cause or reason to deceive or desire to complain of disease with which they do not suffer, whose word would be a guaranty of the truthfulness of their assertions, and who seem to be honest in all they say, and desire to be benefited by advice and treatment.

To place such diseases in the category of hysterical disorders would be a rational sequence, for hysteria is eminently a disorder where simulation is most readily practised.

Charcot, in speaking of hysterical ischuria, says: "This leads me to say a word on *simulation.* You will meet with it at every step in the history of hysteria, and one finds himself sometimes admiring the amazing craft, sagacity, and perseverance which women under the influence of this great neurosis will put in play for the purpose of deception—especially when a physician is to be the victim." Dr. Watson says: "The deceptive appearances displayed in the bodily functions and feelings find their counterpart in the mental. The patients are deceitful, perverse, and obstinate, practising or attempting to practise the most aimless and unnatural impositions." And Hanfield Jones, commenting on this, says: "I believe that the majority of the profession agree with these statements, and that the term 'hysteria' is commonly used to designate a patient whose complaints are considered to be more or less exaggerated, and who is not *bona fide* anxious to get well and cease from being the object of nursing and sympathy;" and further, "call them, if you please, weak-nerved, enfeebled, hyperæsthetic, or neurolytic, or anything which implies that solely their physical mechanism is failing or out of gear, but cast no suspicion on their immaterial part, perhaps braver and stronger than your own, which may never have been tried as theirs has." . . "If, however, no proof of imposition can be discovered, and if the history of the patient shows that she has had much wear and tear of the nervous system, we should be slow to set her down as an hysteric, because she has the classical symptoms more or less markedly." "But when the medical attendant once finds that disorder is simulated, or greatly exaggerated for selfish purposes, he had better conclude that moral treatment is needed, and not medical."

At the same time, to make a common classification of all such troubles under the category or cognomen of hysteria, would not only be wrong in principle, but unwise in judgment. Indeed, this is too often the case, and many times patients are dismissed, after but a casual or imperfect examination, with the remark that there is but little the matter with them, plainly implying that their ailments are purely imaginary, and unworthy of especial attention. That this is wrong, no one will

deny, for it leaves a bad impression upon the mind of the patient, and augurs badly for the healing art, and shows the imperfections of rational therapy; and we should guard against any such presumption, and always give the patient, often times a suppliant for relief, the benefit of the doubt. Errors of judgment or diagnosis, if honest, are excusable—as the eminent surgeon who plunged a trocar in an imaginary ovarian cyst, and found the marks of it on the child after birth—but to pass over the complaints of patients as trifling and unworthy of proper investigation because they are not decidedly manifest or are inappreciable to ordinary observation, makes the practice unfruitful of results, and renders our opinions questionable, and likely to be taken always with a degree of distrust.

With reference to the case reported, there are several points of interest, and the question may arise, whether it was a genuine case of intermittent malarial fever, with its congener malarial neuralgia, a case of simple neurosis, culminating in circumscribed neuralgia, or neuralgia of malarial origin, or a simulated disease, urged on by a desire either for the hallucinating or stupefying effects of morphia.

The prodromal stage she referred to the feeling of malaria, and she described it as a sensation of nervousness and apprehension, sometimes giving her a depressed feeling and a disposition to cry. The paroxysms would come on, she said, about the same time of the day, eleven or twelve o'clock. It was preceded by a certain restlessness, then a shivering or cold feeling, for which she had to go to bed and cover up in blankets, usually taking a dose of whiskey. After some time, varying from one to two hours, fever would succeed, a warmth and glow, and afterwards, towards five o'clock, she would perspire, and then the pain came, for which she especially sought relief. These, she said, were in regular order, the chill always first, and the pain always last. The apyrexias, as will be seen, were at first three days, and then two, then twenty-four hours, and then four days. During the intervals of the paroxysms, she expressed herself as feeling well, with the exception of a little malaise, to overcome which she would usually entertain herself by some home amusement, or go out for a walk.

The pain she described as unendurable, excruciating, unbearable, etc., but expressed herself in regard to it in the most placid, quiet manner, leaving the impression that she bore the severest suffering with the most perfect self-control imaginable. There was no writhing or contorted features, no outcry or other indications of pain, and yet she said she suffered all that could possibly be endured. At this time, the heart sounds were good; respiration regular, but increased; the pulse but slightly accelerated; the temperature normal, or nearly so; the surface a little moist, and the countenance bore an expression of pain or uneasiness. There was only a seeming abandonment to her condition, and a desire for something that would make her oblivious for the time, and which she expected to find in morphia.

Neuralgia is invariably a disease of debility, and we could only expect to find it after a long continuance of the malarial poison, protracting the disease to an unlimited period. In this case there was no exhaustion, no debility or anæmia, no impoverishment of the blood, no want of nourishment. The paroxysms occurred suddenly, after no considerable sickness, at irregular periods, and constituting a fourth stage to a pseudo-intermittent, without a distinct history of malarial poison; and a simple neurosis would probably have resulted only after a long season of depression, anxiety, or other nervous influences acting potentially on a system already weakened by disease, and unable to bear or resist impressions tending to produce this result. There is no doubt there was here a mixed condition, and the main or most prominent symptom was hysterical, although the rhythm of the paroxysms and the clearly expressed pain gave other evidence that there was some other ground for the attacks than mere hysteria, and tended to show it to be either a neurasthenic or neuropathic disease. A prominent consideration in the case is that there was manifest pain, and that hypodermic injections of cold water seemed to relieve and cure it; and if it can be so proven, will it not have a tendency to simplify our therapeutics in the future?

The experiences of Dr. Ponte, related in the *Gaceta Medica di Venezuela* (see *Medical News and Abstract*, Dec. 1881), in which he employed water hypodermically for the relief of pain, seems to come under the same relations as the case reported above, and though he eliminated the imaginative element from the remedy, he does not say whether or not there was any imaginative element or simulation in the cases themselves, and no explanation was given as to the action of the remedy. His cases include intercostal neuralgia, odontalgia, gastro-intestinal neuralgia, with some hundred other cases, treated in the manner described, with good results.

Reference is also made to an article in the *Lyon Médicale* (see *Med. Press*, December, 1881, and *N. Y. Med. Abstract*, Jan. 1882), where Dr. Raymond Tripier employs hypodermic injections of aqua fortis to prevent vomiting of food in phthisical patients. He injects a syringeful of very cold water —either before or immediately after the meal— which often causes the cessation of vomiting which had persisted in spite of other remedies. It appeared similarly to stop vomiting in some dyspeptics, and especially in so-called nervous women who dread morphia, but this latter class should be kept ignorant of the nature of the remedy.

The case reported may have been a simulated disease and there may have been a great desire or longing for the peculiar effects of morphia, at the same time it was not relieved any more by the morphia than by the cold water, and to the cold water may be given the credit of final conquest, in making it unnecessary for the continuance of either remedy, and I present it only to exhibit its novelty and to elicit observations and experiments in the same direction.

1211 F. ST., N. W.

SULPHATE OF ZINC IN CHOREA.

BY E. J. KEMPF, M.D.,
OF FERDINAND, IND.

KATIE SCHMITT, aged fourteen years, was brought to me by her parents for treatment in the spring of 1881. She complained of pains and tiredness in the limbs, accompanied by great restlessness and curious, wriggling, fidgety movements. Her gait is very unsteady, and at times she falls flat to the ground. In walking, the patient seems to drag one leg. She can not keep her hands for a moment in the same place, but convulsively jerks them about. Standing is impossible. The features are almost continually being twisted into the oddest grimaces, and are of a silly, vacant expression.

The parents inform me that this state came on gradually, getting worse by degrees. She could at present hardly feed herself, and when eating would gulp down the food and drink. Dishes or glasses she would at times, when carrying them, involuntarily drop or pitch away. The speech is thick and somewhat affected. The tongue is unsteady, but can be put out with an effort. Saliva would at times dribble from her mouth. Sleep was tolerably sound, the movements ceasing during sleep, though several times she has been found on the floor in the morning. Bowels are constipated. Urine normal, neutral, and offensive. She has no fever and no headache. Scolding her, or fits of crying or fretting, or trying to keep quiet, make matters much worse. The little patient, although very bashful, is lively enough at home; yet she becomes easily fatigued and tired.

I prescribed:

℞. Sulphate of zinc, ... ʒj.
Fl. ex. valerian, ... fl ʒj.
Water, ... fl ʒviij.—M.
Sig.—A teaspoonful thrice daily.

Also—

℞. Aloes suc., powdered, . . . grs. xxx.
Ext. nux vomica, . . . " viij.
Ex. taraxacum, . . . q. s.
Mix, and make thirty pills. Sig.—One or two at bedtime.

The dose of the first prescription was to be gradually increased, so that after the twelfth day she took ten grains of sulphate of zinc at a dose, or thirty grains a day. The fluid extract of valerian was proportionally increased. The purgative pills were given so as to keep the bowels very loose. No regulations in diet were made, the patient being permitted to eat whatever she pleased. An occasional bath was given the patient, and she was instructed to take out-door exercise freely.

On the twenty-seventh day after she came under my treatment, the irregular movements of the arms and legs had nearly ceased. The patient was otherwise almost well. The medicines were continued for some time after she had entirely recovered.

About nine months afterwards, the patient had a slight relapse, but was quickly relieved by a repetition of the medicines.

Three other cases under my care—Jennie C., Mary H., and James L.—have been cured by the same treatment.

Sulphate of zinc, accompanied by active purgation, is a well-established mode of treating chorea, and it is undoubtedly, to my mind, the best treatment that we know of at present.

HOSPITAL NOTES.

VIENNA GENERAL HOSPITAL.

(Service of PROF. SPAETH.)

A CASE OF DIFFICULT LABOR.

(Specially reported for THE MEDICAL NEWS.)

ONE of the most difficult labors, occurring since the first day of the current year, and numbering the 1677th in the "Protokoll" of the second obstetric clinic, has recently terminated.

The woman, M. J., twenty-two years of age, Catholic, unmarried, by occupation a servant, born in Kasejouric, Böhmen, in her second pregnancy, was of medium stature, and presented no abnormalities in the osseous system; constitution and general condition were apparently good. Her previous labor had been easy and had terminated spontaneously. She was uncertain as to the time of last menstruation. The course of the second pregnancy was perfectly normal, until some hours before her admission into the wards of Prof. Spaeth, when premature rupture of the bag of waters had permitted all the amniotic fluid to escape. She entered the lying-in-room 4 o'clock P.M., July 18th, giving the history of premature rupture of the membrane, with entire escape of the amniotic fluid some hours earlier, and that the pains had been felt for the first time, 6 o'clock P.M., July 16th.

Examination, immediately upon her admission, of her breasts and external genitals, revealed nothing of an abnormal character. The abdominal tumor was small in size, the walls tightly contracted around the uterus, while that organ itself was in such a state of constant contraction that the fœtal parts could not be palpated through the abdominal walls. The fœtal heart could not be heard. External measurements gave no evidence of pelvic deformity.

Vaginal examination revealed that the cervix had disappeared, the orificium externum dilated for two fingers, a "conjugata vera" diameter of 10 cm., but the diagnosis of presentation and position of fœtus could only be ascertained after prolonged narcosis. After this procedure it was found that the left shoulder was jammed into the pelvis, lying in front, while the abdomen of the child looked to the abdomen of the mother, the head to the left, and the lower extremities to the right. This presentation and position of the fœtus, according to the Vienna School of Obstetrics, is termed 1st, transverse presentation; 2d, position.

The labor pains, at this time, were weak.

No active treatment was considered advisable, until the mouth of the uterus was completely dilated, which event took place about ten o'clock, 20th of July. During the 19th of July, the woman had a more or less constant elevation of temperature, which reached at one time 41° C. At eleven o'clock A.M., July 20th, Prof. Spaeth and Dr. Ebrendorfer, First Assistant, had a consultation. Prof. Spaeth expressed himself in favor of turning, either by Braxton Hicks' method, if possible, or by the foot. Dr. Ebrendorfer advised decapitation. This advice was rejected, because the head was elevated to such a degree that the introduction of the decapitator would involve inevitable danger of laceration of the maternal tissues. Braxton Hick's method of turning proved also impracticable.

The woman was then chloroformed, placed upon her right side, and Dr. Ebrendorfer, standing to the left side of the woman, introduced the left hand into the uterus, and with an infinite amount of care and difficulty succeeded in grasping the left foot of the fœtus, when, after still greater difficulty in securing rotation of the fœtus, the feet were drawn through the vulva and extraction at once performed. The child was dead, with commencing maceration. The sex was male; weight 3000 grammes; length, 49 centimetres.

The placenta was delivered ten minutes later by Credé's method. The uterine cavity and vagina were thoroughly irrigated with a two per cent. solution of carbolic acid, and iodoform pencils were introduced within the uterus and vagina. Secale cornutum and quinia were exhibited by the mouth in large doses.

The progress of the patient since delivery has been very satisfactory, and recovery is certain.

MEDICAL PROGRESS.

Osteogenesis.—The methods adopted for bringing about a regeneration of bones and joints necessitating resection on account of injury or disease, constitute an advance in surgery of such interest and practical importance as to distinctly merit special consideration. To adopt a measure by which the main support of a limb, when diseased, and not only rendering that limb useless, but also perhaps imperilling life by pain and exhaustive suppuration, can be removed, with not a mere probability, but, in many instances, almost a certain confidence that it will be restored to the patient, is a triumph than which it is hard to conceive one of greater importance among the developments of modern surgery. The subject is of keen interest, and was ably reviewed by Prof. Stokes, in his Address on Surgery, at the meeting of the British Medical Association. Since the time when, in 1865, he witnessed in Lyons many of M. Ollier's experiments, and subsequently repeated them, he has been strongly impressed by what he then learned, and he has since in practice, as suitable cases presented themselves, adopted periosteal preservation in various operations on bones and joints, a procedure with which the names of the eminent surgical trio, Syme, Langenbeck, and Ollier, must for ever be associated. The operative measures on which his experience is based, are resections of the elbow, shoulder, and ankle-joints; resection of the diaphysis of the fibula in its entirety; resection of the greater portion of the ulna; of metatarsal and metacarpal bones; and, lastly, of transplantation of periosteum, as a part of the so-called Indian rhinoplastic operation. Still, though the good results obtained by this practice are, in properly selected cases, not open to question, there can be no doubt as to the existing unsettled condition of surgical opinion in reference to the value of the procedure. This, he believes, arises from a two-fold cause, one being traumatic, from insufficient care being taken during the detachment of the membrane; and the second, the non-differentiation on the part of surgeons of the cases likely to be benefited, and those in which the adoption of the practice is, as a rule, attended with disappointing results. As to its value, when the membrane is comparatively healthy, and the patient young, there can be no question. The activity of bone production and other signally gratifying results of the practice must be acknowledged when performed under these circumstances. These results, however, are not so striking when the patient is an adult. In some cases, no bone production whatever is observed, and in others the osteogenetic process is slow, the product weak, and liable to become absorbed. It should also be borne in mind that, in early life, the membrane has a dual function; one, that of increasing the thickness of bone, and the other the repair of waste. In adult life, it is mainly confined to the latter. This rule, however, is not without exception. He recalled one instance of a man, aged 42, on whom he performed a resection of the upper end of the humerus on account of carious disease. The result was eminently satisfactory; not only was there a reformation of the bone removed, as evidenced by comparative measurement, but also a pseudo-arthrosis so perfect as to enable him now, as he had recently learned, to use his spade, to plough, and perform with efficiency all the ordinary duties of an agricultural laborer.—*Brit. Med. Journ.*, August 12, 1882.

Treatment of Vomiting in Pregnancy.—Prof. C. Braun (*All. Wiener Med. Zeit.*) reports a case to which he was summoned, the patient being regarded as moribund. She was in the first half of her pregnancy and extremely reduced in consequence of intractable vomiting. The physician in charge had decided on producing premature delivery as a last resource. Braun, who has often opposed this practice, decided instead to bathe the vaginal portion of the cervix with a ten per cent. solution of nitrate of silver. This was done, and the surface quickly dried to prevent further cauterization. The success of the treatment was so immediate and so great, that an hour afterward the patient enjoyed a meal of roast veal, and there has been no vomiting since. Prof. Braun thinks that hyperemesis should be expunged from the list of indications for artificial abortion. He has never seen a case of death from hyperemesis. In France, where abortion is frequently induced to relieve this symptom, it is found that the vomiting is thereby stayed in only forty per cent. of the cases, while in ten per cent. the operation has been fatal.—*American Practitioner*, September, 1882.

An Undescribed Fungous Disease of the Skin.—Von Hebra (*Wiener Med. Blätter*, Nos. 39 and 40, 1881) describes a form of dermatomysis which has hitherto escaped observation. It is distinguished by its localization, being found always symmetrically situated on the neck, bend of the elbows, and in the popliteal spaces. The fungus is small, seldom rod-shaped, and no organs of fructification have been observed. The affection is distinguished from herpes tonsurans by its not occurring in rings, by the hairs remaining unaffected, by its chronicity, and by the amount of artificial eczema which it provokes. It is most likely to be confounded with eczema. It was chiefly observed in young anæmic girls with a transparent skin. The treatment consists in first mitigating the eczematous inflammation by diachylon ointment, and then applying anti-parasitic remedies.—*London Medical Record*, August 15, 1882.

Surgical Treatment of Granular Ophthalmia.—The treatment of granular lids is partly medical, partly surgical. M. Brachet, in a paper devoted to the surgical treatment of this disease, records the practice pursued by M. Galezowski (*Recueil d' Ophthalmologie*), in Paris, which appears to have been successful. It consists in the excision, in each eye separately and after the lapse of about a week, of a large fold of conjunctiva from the upper and lower sinus or cul-de-sac. Considerable swelling follows the operation; but as soon as this has subsided—that is, after the lapse of about four days—he applies a crayon of mitigated nitrate of silver to the inner surface of the lids. As a result of this treatment pain diminishes, the cornea becomes clear, and the vision is greatly improved.—*American Practitioner*, September, 1882.

Methods of Amputation.—Prof. Stokes in the Address on Surgery, at the meeting of the British Medical Association, reviewed the different methods employed by different surgeons. According to Von Langenbeck, Trélat, and others, the preservation of the periosteum is attended with advantage. The formation of a periosteal curtain to cover the cut surface of the bone and its medullary canal is believed to act as a shield or barrier against septic agencies, and diminish the chance of the occurrence of some of the secondary calamities, notably osteomyelitis, following amputations. The method he has in some instances adopted, and with success, is, making a somewhat quadrilateral-shaped flap at the membrane and letting it fall over the cut surface of the bone. Another method, that of M. Trélat, is to detach the membrane all round the bone for fully an inch below the point where the bone had to be divided, making, in fact, a sleeve-shaped flap. This plan must, however, materially protract the operation.

This led him to consider some other comparatively recent improvements in the operation of amputation, and to bear his testimony to the great advantages to be derived from the adoption of the principle of long anterior flaps, the chief credit for establishing which belongs to the late Mr. Teale, of Leeds.

Gritti's operation undoubtedly owes its parentage to that of Carden; but, although the retaining of the patella and consequent preservation of the normal attachments of the extensors of the leg is a plan as good as it was original with Gritti, still the details of this method prevented the realization of those advantages which in principle it embodied. Hence the modification which Mr. Stokes terms "supracondyloid amputation"—an operation which, retaining the advantages of Gritti's method, eliminates its defects by lengthening the anterior flap, forming a posterior flap one-third the length of the anterior one, suturing the patella and femur together; and, lastly, and most important of all, by making a high femoral section, but one not involving the medullary canal.

The special advantages that may be claimed for supracondyloid amputation are:

1. That the posterior surface of the anterior flap being covered with a natural synovial membrane, the chances of suppuration and purulent absorption are diminished.

2. Any possibility of the split patella shifting from its place on the cut surface of the femur is prevented by the high femoral section, and by suturing the two bones together.

3. The vessels are divided at right angles to their continuity, and not obliquely, as in other flap operations.

4. The existence of a posterior flap diminishes the chances of any wide gaping of the wound; while the anterior flap, being oval, increases the chances of the stump tapering gradually towards its extremity and assuming the form of a rounded cone.

5. The preservation of the normal attachments of the extensors of the leg.

These advantages embody those of both flap and circular amputation of the thigh, and, at the same time, eliminate their defects.—*Brit. Med. Journ.*, August 12, 1882.

Acute Miliary Tuberculosis of the Pharynx Cured by Iodoform.—M. Gouguenheim reported the following case at the meeting of the Société Médicale des Hôpitaux, on July 28th. He was called to attend a pregnant woman suffering from pain in the throat, and found a condition of ulceration of the anterior half arches and enormous hypertrophy of the uvula, which reached to the laryngeal orifice. The tuberculous nature of the ulceration was established by microscopic examination of the amputated uvula; there was no sign of pulmonary tuberculosis. The lesion was extremely painful and the prognosis seemed to Isambert to be very grave. M. Gouguenheim prescribed ethereal solution of iodoform locally, under which the disease rapidly disappeared. A reappearance of the disease was treated in the same manner with an equally successful result.—*Gaz. Hebdom. de Méd. et de Chir.*, Aug. 4, 1882.

Naphthaline.—Dr. Fischer (*St. Petersb. Med. Woch.*, No. 16, 1882) has made investigations into the uses of this article in all directions. It has been in use as an antiseptic in the surgical clinic at Strasburg; and the results arrived at by Fischer are that naphthaline is a very serviceable antiseptic against both bacteria and mycetes. He even believes it to have a certain influence on inorganic ferments. Some kinds of decomposition are checked in a higher degree by naphthaline than by iodoform. Prof. Kohts observed that in the children's wards for diphtheria and scarlet fever not a single case of infection by contact occurred during the six weeks that they were strewed with naphthaline; this showing that it is also operative as a gas. It is further an active poison to all insects, *e. g.*, fleas, lice, acari, flies, midges, moths, and spiders. Against scabies it is used with equal parts of vaseline; birds and mammals bear it very well, although, when large doses were given to dogs internally, dysentery set in. Sometimes the urine is darkened by naphthaline, though never so much as by carbolic acid. It passes unchanged through the urine, but poisoning by it has never been observed, neither does it produce local irritation, although powdered directly upon wounds and ulcers. Its chief advantage is that it is fifty times cheaper than iodoform. One soon becomes used to the smell. In Nos. 8 and 9 of the *Berl. klin. Woch.*, 1882, Fischer further gives the manufacturers' names from whom the best forms of this useful substance can be obtained, which are here enumerated, as they may prove useful. 1. For direct application to large wounds, for packing cloacæ, abscesses, etc., the best form is the naphthalinum albissimum resublimatum of Trommsdorff, chemical factory at Erfurt, price about 1.20 marks per kilogramme; 2. For lighter injuries, and for impregnating the dressings: *a.* The crystallized naphthaline of Trommsdorff, price 60 marks for 100 kilogrammes; *b.* Naphthalinum resublimatum of Ohlgardt and Co., chemical works at Kehl, Baden, about 50 marks for 100 kilogrammes. Besides these, very good preparations are made by Merk in Darmstadt (Hesse), Kuhlbaum in Berlin, etc.—*London Medical Record*, August 15, 1882.

Supra-pubic Lithotomy.—M. Le Dentu reports a successful case of supra-pubic lithotomy in a man aged 71 years, and gives the following *résumé* of his views concerning the operation:

1. Previous distention of the rectum and bladder facilitates the finding of the latter; in subjects affected with inertia of the bladder, the distention should not be pushed too far.

2. The employment of the thermo-cautery will usually prevent infiltration of urine, and favors adhesion between the soft parts and the vesical wall.

3. It is important not to disturb the fatty tissue generally found in the retro-pubic space, and not to incise the bladder behind the pubis, as recommended by Velpeau. Slight tension on the skin, from below upwards, facilitates the separation of the peritoneum and permits of safely enlarging the wound.

4. The use of M. Anger's vertebrated conductor, pressed against the anterior wall of the bladder, gives a good point of support for the thermo-cautery or bistoury.

5. Suture of the soft parts, not including the bladder, should be absolutely avoided, with the exception of one or two superficial stitches to diminish the size of the wound in the skin.

The suture of the bladder, together with the abdominal walls, is dangerous; since, if the stitches pull out of the bladder, infiltration of urine under the superficial layers will be sure to occur. It is especially dangerous in the aged, since it necessitates the use of the retained catheter, or repeated catheterization, both of which proceedings are attended with great danger.

It offers the same disadvantages in adults and children, and perhaps does not even have the advantage of facilitating cure.

It is, however, advisable to insert a stitch at the inferior angle of the vesical wound, and one or two stitches laterally at each side of this angle, so as to unite the musculo-fibrous layers of the bladder, and prevent the passage of urine into the retro-pubic space.

6. The means proposed for conducting the urine through the urethra are useless and dangerous. The insertion through the abdominal wound of a double siphon formed of rubber tube, pierced with holes in the sides, ensures the removal of the entire quantity of urine formed.

7. The retained catheter should only be employed when the patient is out of danger; unless there is some special indication for its use, it should not be used in the first few days after the operation.

In some cases it is to be preferred to repeated catheterization, while in others the reverse holds. In all cases its use must be frequently suspended, since patients usually have great difficulty in learning to tolerate it.

By means of these precautions it is thought that the danger of the formation of a urinary fistula is reduced to a minimum.—*Gaz. Méd. de Paris*, July 1, 1882.

The Selection of Anæsthetics.—In the Address on Surgery at the meeting of the British Medical Association, Prof. Wm. Stokes said that whatever anæsthetic the surgeon selects—whether it be chloroform, ether, or both combined, bichloride of methyline, or nitrous oxide gas—we must admit that, even with the most careful precautions as regards the condition of the patient generally, the anæsthetic selected, the amount of it used, and the mode of its administration, the gauntlet of peril has still to be run. In truth, it is hardly to be expected that an agent which can so rapidly and completely paralyze our senses should not be attended with peril. Of the two anæsthetics, however, that surgeons as a rule mainly rely on—ether and chloroform—much has of late been done to diminish risk by limitation of the amount of the anæsthetic used; by the gradual introduction of it into the system; by the avoidance of ether in infancy and extreme age, in the puerperal state, in hysteria, and also when there is reason to suspect the existence of any acute or chronic form of renal or pulmonary disease. In the use of chloroform the ever-present risk of cardiac paralysis appears to be increased when any functional or organic disease of the heart is present, and is, therefore, in such cases, distinctly contraindicated.

Although the number of accidents connected with the use of anæsthetics is fortunately very limited, still he felt sure that by more accurate knowledge of the facts he has mentioned, by entrusting the duty of administering anæsthetics solely to persons of experience and judgment, and by a stricter adoption of the rule so happily formulated by Mr. Jonathan Hutchinson in reference to the desirability of using chloroform in cases below six and above sixty years of age, the number of these regrettable accidents would be still further largely diminished. In the majority of cases, however, he would unhesitatingly prefer ether. In using it, there is greater economy of time; it is, with the necessary precautions taken, safer; there is, as a rule, less sickness, and return to sensibility is slower. To obtain these advantages—which, with others, have been so well and systematically formulated by Mr. Teale (*British Medical Journal*, March 11, 1882)—regard must be largely had to the method employed of administering it; and he is of opinion that one in which the air is rebreathed by the patient, as in the inhalers of Morgan, Ormsby, and Clover, should be preferred, as so great an economy is effected thereby, not alone of ether, but of what is of far greater importance, of heat in the air-passages, the inspiration of a large quantity of cold ether vapor tending to induce respiratory syncope.

In these instruments, the inhalation of a combination of ether vapor and carbonic acid gas occurs. It does not, however, appear to be clearly ascertained whether in this fact there is the introduction of an additional element of danger or not. Opinion on this point is still greatly divided. One would say, *à priori*, that there was; but experience has not established the fact.—*British Medical Journal*, August 12, 1882.

Artificial Production of Monstrosities.—At the meeting of the Académie des Sciences M. Dareste alluded to the interval of time, which elapses between the laying and incubation of the egg, as a cause of abnormal development of the embryo, and said that some recent experiments had enabled him to confirm his views. Although, as is well known, the laid egg preserves for some time its germinating power, there finally arrives a time when the cicatricula becomes disorganized, and consequently incapable of producing an embryo. But between the time when the cicatricula is capable of producing a normal embryo, and the time when it is disorganized, there exists a period in which, though living, its vitality is so altered that it is only capable of producing an abnormal embryo.—*Rev. Scientifique*, Aug. 12, 1882.

Diagnosis of Syphilitic Disease of the Lung, by Examination of the Sputa.—Dr. J. E. Güntz, of Dresden, in a paper on the diagnosis of syphilis of the lung (*Memorab.*, Heft 4, 1882), refers to a paper lately published by Cube in Virchow's *Archiv*, containing the particulars of a case of supposed tubercular phthisis, which was afterwards diagnosed to be syphilitic by the detection of gummy material in the sputa, and in which recovery took place. The author also describes a similar case under his own care, in which the diagnosis was confirmed by microscopical examination of the sputa. A man, aged 35, who had contracted syphilis five years before, came under observation with a gumma on the leg, and with signs of consolidation over a small area in the lower lobe of the left lung on its posterior aspect. The patient recovered for a time under injections of bicyanide of of mercury. A year and a half later, the man strained himself in lifting a heavy weight, and this was followed by hæmoptysis and shortness of breath, without fever or loss of appetite. The previously affected area at the back of the left chest had increased in size, and there were the physical signs of a hemorrhagic infarct. Dr. Güntz presumed that bleeding had occurred around an old patch of syphilitic deposit in the lung. The patient finally recovered. The material which was coughed up, after being freed from blood by soaking in alcohol, showed under the microscope a mixture of granular detritus, groups of granules, cells, fatty matter, etc., some of the specimens showing the appearances depicted in Lancereaux's work on syphilis. Neither blood-corpuscles, nor vessels, nor lung tissue were detected. Some of the preparations were sent to

M. Lancereaux, who informed the author that he found small round cells colored by carmine, such as are found in gummy formations, and that he, therefore, agreed with Dr. Güntz as to the syphilitic nature of the change. The author concludes with the remark that this is only the second case on record, in which the existence of syphilitic disease of the lung has been proved during life, by the coughing up of gummy fragments, and their detection in the sputa.—*London Med. Record*, August 15, 1882.

THE FUNCTIONS OF THE PHRENIC AND INTERCOSTAL NERVES.—At the meeting of the Société de Biologie, held July 29th, MM. HÉNOCQUE AND ELVY presented a memoir, in which they considered the reciprocal effects of sections of the phrenic and intercostal nerves on respiration. While they found that section of the last eight inferior intercostal nerves produced very little change in the character of the respiratory, they drew the following conclusions as to the action of the phrenic nerve:

1. Section of one phrenic nerve modifies the respiratory rhythm of both sides of the chest.
2. The section of the inferior roots on both sides, produces less disturbance than the division of a single superior root on one side.
3. Division of the upper root of the phrenic nerves on both sides, produces the most marked modification of the respiratory rhythm.
4. Section of the upper roots on both sides, produces an exaggeration of the inspiratory movement, lasting more than three quarters of an hour.
5. Section, irritation, pinching or ligature of the upper phrenic root produces great pain.
6. The difference in action of the two roots on the action of the diaphragm, appears to lie mainly in the different degrees of amplitude of inspiration.—*Gaz. Hebd. de Méd. et de Chirurg.*, August 11, 1882.

THE HYGIENIC VALUE OF ANTISEPTICS.—At the meeting of the British Medical Association, PROF. STOKES, as an instance of the hygienic value of the antiseptic practice, mentioned that, in the hospital to which he was attached, the building was a very old one, and was not constructed originally for a hospital. None of the more modern arrangements, now considered so essential, as regards heating, light, ventilation, etc., exist. It is situated in a poor, very densely populated part of the city, with tenement houses, dairy yards, cattle sheds, and stables in its neighborhood; and some of the houses in its immediate vicinity have been designated by the Medical Officers of Health as "fever nests." When he was a student there, erysipelas and pyæmia were not unfrequently observed after operations even of no great magnitude; hospital gangrene, too, he has seen several instances of; in fact, these three diseases constituted a grim trio, of which the surgeons had not unnaturally a dread. Let it not be thought that the occurrence of these was in any way to be attributed to want of care and attention to cleanliness. No cases could in this respect be more conscientiously or carefully managed. What now exists? Hospital gangrene is an extinct disease, nor have we observed, during a period extending over six years, a single case of erysipelas, septicæmia, or pyæmia following an operation in which the practice of Lister was accurately carried out; *accurately*, for everything depends on that. The practice has been well compared to a coat of mail, which secures the wearer as long as it is perfect, but any missing link in which may admit the *lethalis arundo*.

Similar testimony to what he and his colleagues can state has been given by many foreign surgeons of eminence, among whom he mentioned Von Nussbaum, Bardeleben, Thiersch, Von Langenbeck, Volkmann, Esmarch, Saxtorpf, Championnière, and many others. —*British Medical Journal*, August 12, 1882.

BROMIDE OF POTASSIUM IN DIABETES MELLITUS.—The idea of employing the bromide of potassium in the treatment of diabetes mellitus is not a new one. It was first advocated by Begbie, in 1866, who attributed the cure of a case of diabetes to this remedy, but the numerous failures with it subsequently reported threw the drug into discredit. M. FELIZET has endeavored before the French Academy to renew confidence in bromide of potassium for this purpose, and quotes a series of cases of diabetes, in which it was employed with great success, but even he is the first to declare that this remedy cannot be regarded as a specific, a useless precaution, as the very multiplicity of drugs now recommended for diabetes proves that no one of them is a specific.—*Gaz. Med. de Paris*, Aug. 12, 1882.

THE UNION OF NERVES.—M. GLUCK, not long ago, suggested the use of Neuber's "ossein" drainage-tubes (composed of decalcified bone) as a means of promoting the union of divided nerves. His attempts were, however, not successful. M. Vanlair has lately repeated the experiment, avoiding as far as possible any conditions which might have interfered with the results in Gluck's cases, and he has been more successful than the Berlin surgeon. At the first attempt he obtained, in four months, the regeneration of a nerve filament no less than five millimetres in length. From other experiments he has arrived at the conclusion that it will be possible to reproduce nerve segments of almost any length. The details of the operative procedures are not described in M. Vanlair's paper, which was communicated to the Académie des Sciences, and is chiefly occupied by some facts which, proceeding in this manner, he has ascertained regarding the process of regeneration of nerves. These facts corroborate the conclusions of Eichhorst, Ranvier, and Helm, that the regeneration is by a process of peripheral budding. He has also ascertained that a partial restoration of muscular activity, correlative to an anatomical regeneration of the nerve fibres, may occur a long time before the return of cutaneous sensibility. The new growth always commences in the marginal zone of the fasciculi, and only reaches very slowly the axial bundle. Hence the conclusion is drawn that the efficient cause of the proliferation is not the direct irritation due to the division, but the inflammation which spreads from the sheath in consequence of the injury. The maturation of the newly formed fibres proceeds from the periphery towards the centre; the inferior half of the intercalated segment resembles the normal type of structure much more closely than the superior half. The relations which Vanlair has traced between the new segment and the peripheral portion of the nerve are as follows. A distinct fasciculus in the inferior part of the segment may pass through the junction, and then emerge as an altogether independent nerve, to ramify in an adjacent muscular mass. Other bundles pass along the dissociated fasciculi of the peripheral portion without penetrating into their interior, so that a section presents two distinct circumscribed portions, one constituted by young, living, almost microscopic fasciculi, directly continuous with those of the intermediate segment; the other composed of larger fasciculi with degenerate fibres, belonging to the old peripheral segment. Another part of the fibres of the intermediate portion separate and are lost in the connective tissue which forms a swelling at the junction of the old and new portions. Lastly, a small number of new fibres enter the fasciculi of the degenerated fibres,

and pass either into the empty Schwann's sheaths or into the interstices between them, and can be traced for a certain distance from the point of section. Thus the peripheral end seems to be the channel for only a limited number of the new nerve fibres, and to constitute rather an obstacle to the regular progress of the new elements. These observations, if accurate, seem to show that it is a mistake to endeavor to bring closely together the extremities of divided nerves. What is necessary is that the regenerating nerve should be enclosed in some limiting structure such as a Neuber's tube.—*Lancet*, Aug. 12, 1882.

ANTISEPTICS IN EXCISION OF THE KNEE-JOINT.—In the Address on Surgery at the meeting of the British Medical Association, PROF. WM. STOKES said that one of the best tests, if not the best, for the value of antiseptic practice is resection of the knee-joint, as there are so many circumstances that militate against immediate union being obtained after it. In the first place, the cases requiring so formidable an operation are, as a rule, in a condition of great physical exhaustion consequent on long confinement, and probably protracted suffering of mind and body. The wound is of necessity a large one; the operation occupies a considerable time; two large freshly cut bone surfaces are made, between which union is to take place; and, lastly, there is the great difficulty of keeping, no matter what appliance be adopted, the limb absolutely at rest during the process of union. Before the adoption of Listerism, the surgeon anticipated that four, six, or eight months, or longer, would elapse before union took place, and it was always a subject discussed at consultations on these cases, previously to operation, whether the patient would have strength to endure so protracted a suppuration. As an illustration of how changed matters are now, in a series of fourteen of his cases of excision of the knee-joint, the wounds in nine of them united without a trace of pus production; and in the last of them only two dressings were required subsequent to the one applied at the time of the operation, and in seven weeks after the patient was up and going about. Another antiseptic triumph was the case of a boy with extensive necrosis of the fibula, sinuses, and suppuration existing at the time of the operation. He excised subperiosteally the diaphysis of the fibula, and the case pursued a perfectly aseptic course, the evidence of new bone-formation being also incontrovertible. From the fact of there being no pus production subsequent to the operation, notwithstanding the pre-existence of suppurating sinuses, a special interest attaches itself to this case. He can only account for this exceptional circumstance as a result of the careful washing of the sinuses by carbolic acid and zinc chloride solutions. A still more remarkable case was that of a youth who was under his care last November. He trod on a triangular piece of glass, which, having passed deeply into the sole of his foot, was with difficulty extracted. An acute suppurative inflammation, involving the ankle-joint and extending as far as the knee, was the outcome of the injury. There was indicated, by both pulse and temperature, very high fever, and the condition of the patient was most critical. He made free incisions under the spray on both sides of the ankle-joint, and gave exit to pus and synovia in large quantity. Into these openings he injected a weak solution of eucalyptol, and inserted Neuber's drainage tubes. Next day he found pulse and temperature normal, and from this the case pursued an aseptic course, and in less than a month after the patient left the hospital, the foot being in a perfectly normal condition, all motions of its joints being free, and unattended with the slightest stiffness or pain. In another case, he cut down on an ankylosed hip (the limb being so flexed as to be perfectly useless to the patient), and divided the neck of the femur with an osteotome, and straightened the limb. The wound healed without pus production, and a freely movable false joint was formed, and the patient is able to walk several miles without inconvenience.

Another antiseptic triumph was obtained in two cases of amputation at the hip-joint. In one of these there were pre-existing sinuses and profuse suppuration, and, notwithstanding, he succeeded for eight days, during the most critical period of the patient's convalescence, in keeping the wound aseptic, and preventing the occurrence of surgical fever. The result in the second case was more remarkable; not only during the healing of the wound was there no pus production, but pulse and temperature hardly ever rose beyond the normal standard. The skin was unbroken, and on the evening previous to, and also on the morning of, the operation, the patient had a eucalyptol bath. Looking at these few cases—few, not because he could not largely supplement them, but because they were sufficient for his present purpose—he asks, could such results have been obtained previous to the Listerian teachings of the principles and practice of antiseptic surgery? There can be but one reply—impossible.—*British Medical Journal*, August 12, 1882.

ORIGIN OF THE OLFACTORY TRACT AND STRUCTURE OF THE OLFACTORY LOBES.—SIGNOR GOLGI, in the last part of the *Archives Italiennes de Biologie*, states that he has made a series of sections through the olfactory lobes, with a view of determining the connection of the cells and strands of the olfactory lobes. He finds that there is in man and mammals a superficial layer, continuous with the tractus olfactorius, which gradually becomes thinner posteriorly and stretches towards the gyrus hippocampi; a thicker layer of gray matter, rich in ganglion cells; and a layer of nerve fibres, not very clearly defined from the deeper layer of ganglion cells with which they are connected. He maintains that two kinds of nerve cells exist in the gray substance of the lobi olfactorii—one set the processes of which divide into extremely fine fibrils, and are lost in the delicate plexus of the neuroglia, and a second set the fibres of which, though they divide and subdivide, yet preserve their individuality. The fibres of the tractus olfactorius sometimes curve away from their longitudinal course and enter the superjacent gray matter obliquely. The deeper fasciculi of the lobus olfactorius may be traced to the corona radiata, and some, perhaps, into the anterior commissure. Some of the nerve fibres of the olfactory tract originate in the plexus of fine nerve processes of the lobi olfactorii, but are not directly continuous with the ganglion cells of this region. Other fibres, again, are directly continuous with the processes of the ganglion cells.—*Lancet*, August 12, 1882.

LUXATION OF THE CERVICAL VERTEBRÆ.—At the surgical clinic of PROF. GUSSENBAUER, on July 29th, a patient was presented, who, the day before, had fallen into a ditch, and struck on his head, which was violently flexed on his chest, producing a lateral subluxation of the second, third, and fourth cervical vertebræ. The entire cervical spinal column moved together, on attempts to move the head, causing great pain, while lateral movements of the head were impossible. Examined through the mouth, a marked depression was found opposite the second and third vertebræ. The reduction of the luxation, which is generally very dangerous, on account of the liability of compressing the spinal cord, was accomplished by continued extension of the head, by means of a weight, until the normal position and mobility of the neck were attained. Massage and passive movements, which were first tried, were of no avail.—*All. Wiener Med. Zeit.*, August 1, 1882.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE, ... $5.00.

SINGLE COPIES, ... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made at the risk of the publishers, by forwarding in REGISTERED letters.

Address, HENRY C. LEA'S SON & CO.,
Nos. 706 & 708 SANSOM STREET,
PHILADELPHIA, PA.

SATURDAY, SEPTEMBER 2, 1882.

THE SURGICAL TREATMENT OF PERITYPHLITIS.

NOT every case of perityphlitis needs the knife. More than one-half of the cases recover under purely medical treatment. It is nothing rare to see a case with sharp fever, the right leg painful on motion, and possibly drawn up, pain localized usually in the right iliac fossa, a more or less well-defined tumor in the same region, which is tender on pressure, and increases up to a certain size, and then, after a few days, subsides, the case thus terminating by resolution without suppuration.

But, on the other hand, not every case has so happy a termination. A considerable, and, in fact, we might well say, a large number of cases go on sometimes swiftly, at other times slowly but surely, from bad to worse; the tumor increases in size, and finally bursts either externally (strange to say, its least fortunate course), or into some hollow viscus, and the patient recovers after a tedious convalescence, during which he has run the gauntlet of many perils; or more frequently dies, either as a result of exhaustion or peritonitis, or hemorrhage, or some other equally avoidable evil.

Previous to 1867, the treatment of perityphlitis was well-nigh wholly medical. If an unmistakable abscess formed, of course, like any other abscess, it was either opened or more often allowed to discharge spontaneously. Little, if any thing further, was done surgically, although twenty years before Hancock had operated successfully in one case. But in that year Willard Parker established the surgical treatment of the disease, and scarcely any improvement has been made upon the method he then proposed. We call attention to it not to suggest improvements, but to point out the fact that so simple, so useful, and so successful an operation should be far more frequently resorted to, and to indicate some of the conditions which would make it not only justifiable, but advisable. Happily, it is growing in favor, and many of our readers will be able out of their own experience to confirm our views. In June last, one of the few cases done in this city was reported to the County Medical Society.

The operation proper is not commonly a difficult one. The incision should be usually about three inches in length, parallel to and a little above Poupart's ligament. Dividing successively the skin, superficial fascia, the aponeurosis of the external oblique and the bellies of the internal oblique and the transversalis, the direction of whose fibres is a ready guide in their differentiation, we reach the transversalis fascia. If fluctuation or other undoubted evidence of pus now be found, this fascia should be incised at once. If the case be still doubtful, a hypodermic syringe or the aspirator needle may be inserted at different points to find the pus, and once found, the knife may lay the cavity widely open, or, after a small opening, the dressing forceps may be inserted, opened, and withdrawn, thus tearing a vent, as practised by Buck, and since recommended by Lister in other cases, especially those in which vessels might be injured by the knife. If no evidence of pus be found, then the wound may be packed, and the subsequent treatment be guided by circumstances; usually a few days will release a considerable quantity of pus.

The discharge will vary in amount from a couple of ounces up to even a gallon. It is usually very fetid, and in it may sometimes be discovered the foreign body or fecal concretion which has been the cause of the mischief. In a sac formed only by inflammatory adhesions, and especially if it be recent, it is wise not to do too much fingering. Satisfied with a free exit to the pus, it is best merely to wash out the cavity gently by carbolized water; dress with ample absorbent material—preferably the antiseptic, and indeed the whole treatment ought to be such—give the lightest kind of fluid food, and appropriate remedies, and the result in by far the larger part of the cases will be most satisfactory both to the surgeon and the patient. The discharge will be abundant for the first twenty-four hours at least, and during this time the wound should be dressed twice. Of course, thorough drainage should be established either by a single or double rubber tube, but, as Stephen Smith has recently shown, its too long continuance in any wound is hurtful. Hemorrhage is not apt to be severe; in fact, very often not a single artery will require a ligature. The cavity must be made, of course, to heal from the bottom.

When shall such an operation be done is perhaps

the first question to be answered. Shall we wait till a chill, fluctuation, and other evidences of pus are present? If we do, we shall often wait till irreparable injury is done, either by extensive burrowing or by perforation of the bladder, rectum, vagina, or other hollow organ. In some cases it can hardly be said that a well-defined tumor exists, but merely a diffused, poorly limited swelling, with a brawny, hardly doughy, feel, with no fluctuation, and but little œdema, and that, too, long after pus has formed. Yet these cases should be operated on, and almost invariably pus will be evacuated in large quantity. The swelling is not always dull, and at least on superficial percussion may be even tympanitic. In explanation of the foregoing peculiarities we must remember that the pus begins to accumulate usually behind the hollow cæcum; that the wall of the abdomen is separated from the bowel by the peritoneal cavity; and that the abscess, therefore, only compresses the cæcum and affects the abdominal wall secondarily, and after it has reached a certain size.

The earliest operation done has been on the fifth day, but it has also been done successfully after even two years. When the disease has existed for five days or more, as Parker and Burger have shown, the abscess is already a circumscribed one, and diffused peritonitis is then a danger not likely to follow, either spontaneously or as a result of careful operative interference.

The rule for such interference may be stated in a general way as follows: Given a case of perityphlitis which has existed, say for a week or more, no operation should be done as long as the patient is improving, although only gradually, or continues in about the same condition, or until so long a time a time has elapsed as to make it doubtful whether resolution can be expected. *Per contra*, given a similar case of a week's duration or more, with the symptoms we have described, and going from bad to worse, an exploratory operation should be done which will almost certainly lead to the opening of an abscess, although the physical signs of such an abscess may be obscure, or even wanting.

The remote results are usually most favorable, the patient regaining health and strength very rapidly. Troublesome sinuses, however, occasionally remain. Weber reports one case followed by a hernia; and Mason, Partridge, Keyes, and others report cases of recurrence of the disease; the last, indeed, giving the most extraordinary history of subsidence and recurrence of the disease that we know of.

CHINESE MEDICINE.

DR. D. J. MACGOWAN, in his discursive, but highly interesting, "Report on the Health of Wênchow for the Half-year ending September 30, 1881," gives us some very curious glimpses into Chinese medical practice, which illustrate the contradictory aspects of the singular civilization of the Flowery Land. On the one hand, we have records of epidemics extending as far back as A.D. 95, and "more than a score of centuries before Hippocrates wrote of 'critical days,'" the "Yellow Emperor," Hwangti, discoursed learnedly on the same subject; while Dr. Macgowan assures us that the medical literature of China displays great acumen and powers of observation. On the other hand, nothing can well exceed the superstition and fetishism which prevail in actual practice among the people. Pestilence is universally regarded as the work of special demons, not only by the uneducated but by the literati and governing classes. This belief is of old standing, for it is recorded that in 541 A.D., the Emperor Kautsu, on the appearance in the sky of an apparition of "five mighty ones," was told that they were Heaven-sent demons, agents of the five epidemics (of spring, summer, autumn, winter, and pestilences in general), robed respectively in green, white, red, black, and yellow, and each bearing a utensil, such as a hammer, ladle, sword, etc. A great epidemic followed throughout the Empire, in the hope of assuaging which, Kautsu erected a temple and offered sacrifices to the demons, on each of whom he conferred the military title of general. Efforts are still made to propitiate these demons by processions in which they are borne magnificently arrayed, and earnest devotees are found to offer the sacrifice of suffering by bearing for weary miles pots of incense suspended by hooks inserted in the flesh of the arm, which is kept extended by an iron rod passing from the hip to the hand.

Much of this is probably the result of the corruptions of Buddhism and Taoism, for Confucianism, the religion of the governing classes, imparts teachings of a much higher order. Enlightened officials are therefore sometimes found who take a more sensible view of the case, such as the Governor of Wênchow, in the sixteenth century, whose province for several decades had been ravaged by an annual epidemic, until the inhabitants feared to venture out at night lest they should encounter the demon personally. He finally, in 1579, assembled the people and gave them a lecture on sanitary matters, inculcating a reformation in manners, food, and mode of life; and though he permitted the erection of a temple to the five demons, which the zeal of the people accomplished within a month, and which is still standing, his enforcement of the proposed reforms shortly afterwards put an end to the visitation. Even more rationalistic was Chang Tzüchi, Governor of Changchau, when it was depopulated by a pestilence in 1295. He established a dispensary for the gratuitous distribution of medicines, but

found no custom, as the people preferred making offerings in the Temple of the Demons of Pestilence, purchasing charms and amulets of the bonzes, and employing them as exorcists. Whereupon Chang Tzüchi fuddled his soldiery, and before they were sober enough to recognize the sacrilege, he caused them to level the temple to the earth, and he finished the matter by scourging the priests and setting them adrift. But, as Dr. Macgowan remarks, "unfortunately rulers of that stamp have neither successors nor imitators."

Yet Confucianism also lends itself to the propagation of these superstitions, through its admission of ancestor-worship as the only form of religious service. The five demons whom Kautsu promoted to the rank of general seem to have been regarded as the spirits of departed men, and the medical profession in China habitually resort for assistance to the deified spirits of renowned practitioners of the past, who have temples dedicated to them, and who are dignified with the title of Yo Wang, or Medicine Princes. The earliest of these is Pien Ch'iao, who flourished in the fifth century B. C. He was originally an innkeeper, who had the luck to encounter a spirit, from whom he received a drug which, taken daily for a month, so spiritualized him that he was able to see through stone walls, and thus became competent to form a correct diagnosis of the most recondite disorders of the viscera, leading to astonishing cures. It is melancholy to have to add that he was assassinated by the court physician of the Prince of Tsin, whose jealousy he had aroused by curing the prime minister after the physician had abandoned the case as hopeless. Professional heart-burnings to-day are, doubtless, as bitter as they were then, but fortunately they are not manifested in such vigorous style.

We shall hope to hear more from Dr. Macgowan, who is evidently a zealous cultivator of the wide and curious field of observation that lies before him.

THE SUBCUTANEOUS INJECTION OF ETHER.

It should be more generally known that ether injected subcutaneously has a powerful stimulant effect, and is remarkably efficacious in cases of extreme depression of the powers of life. It has long been used to a limited extent in such cases, but increasing experience has enlarged the domain of its application. In adynamic pneumonia, in fevers when failure of the vital powers is threatened, in the puerperal state, in cases of thrombosis of important vessels, the injection of ether has been lately used with singular benefit. Besides, as a stimulant in conditions of depression, it has important applications as a hypnotic and local anodyne. In cerebral excitement and wakefulness, accompanied by depression of the arterial circulation, it is most useful. In the more chronic cases of superficial neuralgia, as sciatica, lumbago, intercostal pain, zoster, etc., ether injected in the neighborhood of the affected nerves often gives surprising relief.

There are contra-indications to its use. It is not proper in the cases of cardiac depression due to chloroform or ether narcosis, and yet it has, in the confusion incident to such an event, been freely injected on the cessation of the cardiac or respiratory movements. Under similar circumstances, alcohol has also been freely injected subcutaneously, but this practice is equally improper—and both for the obvious reasons that these are synergistic agents. Ether, subcutaneously, is also not a suitable remedy when there is arterial excitement with power.

The technical details are simple. Ether must be injected with a glass or metallic syringe. Rubber and celluloid are damaged by it. As ether dissolves the oil with which the piston is lubricated, the syringe should always be put in order after ether has been injected. It is a useful precaution, also, to see that no particles of dirt or of leather are taken up with the fat. Vaseline appears to be the safest lubricant under these circumstances. From ten to sixty minims is the dose—fifteen minims being the quantity most frequently injected. Some smarting attends the operation, but if the operator is careful in withdrawing the needle to press on the orifice tightly, to prevent the ether escaping, much smarting will be thus obviated. A puffy swelling is caused by the vaporization of the ether, but this presently subsides, and only rarely is an indurated knot formed. An anæsthetic and analgesic area of limited extent surrounds the puncture.

The ether used should be of good quality—as good, indeed, as that now employed for inhalation. The number of times injected will depend on the character of the case, but there appears to be no reason why it may not be injected frequently. Three or four times a day has been the rate in cases of adynamic pneumonia. When sudden, extreme depression of the heart is to be overcome, ten or twenty minims can be injected every five minutes, until some result is reached.

The systemic effect is that of a stimulant; the action of the heart is increased, the surface grows warm, and the nerve centres and the organs of the body in general functionate more quickly and powerfully. The curative results of the subcutaneous use of ether are not only different in degree, but in kind, from the stomachal administration of the same agent. This fact must be recognized to obtain a correct notion of the utility of this practice.

HYDROPHOBIA.

The recent presentation to the French Academy of Medicine of a case of so-called hydrophobia, cured by pilocarpine, and the opinion held in regard to it by M. Bouley, probably the best informed person upon this subject in France, or anywhere, prompt us to make some remarks upon this exceedingly obscure disorder.

M. Bouley did not believe the case referred to to be one of hydrophobia. For such an opinion two good reasons are apparent: first, hydrophobia cannot be cured by pilocarpine, or any known drug; and, second, the symptoms of this case were not, as the reporter, Dr. Denis-Dumont, supposed, pathognomonic of hydrophobia.

A man, a woman, and a girl were bitten by the same dog on the same day. The woman died hydrophobic (?) in thirty-six days. The girl has not suffered. The man, on hearing of the woman's death, became excited, took to the fields, ran about wildly, and tried to bite everything that came in his way. On being taken to the hospital at Caen, he showed great dread of fluids, and spasm of the throat on attempting to drink.

These are well known popular symptoms of hydrophobia; but, as is common in imitative diseases, the picture is too strongly drawn—the *idea* is carried out, but the typical course is left behind. Horror of fluids is not a pathognomonic symptom of hydrophobia, spasm of the larynx or pharynx usually occurs, but running wild is almost unknown, and attempts at biting are almost if not quite as rare. Actual biting has, we think, never taken place.

The acts enumerated are not evidences of hydrophobia, but of an excited and perverted nervous system. This is the more obvious in cases like that before us, where the attack was precipitated (upon one who, at the time of the bite, had been sufficiently impressed to cauterize the wound with nitric acid) by hearing that another person, bitten by the same dog, had died with symptoms of hydrophobia.

The fact is, there is no subject in the whole field of medical investigation which is so strange and mysterious as hydrophobia. It would be idle to assert, in the face of recent experiments with the saliva of healthy human beings, that the inoculation of the saliva of an enraged or diseased dog may not cause sickness or death to other animals, of various species. But the plain truth is, that no more is certainly known to-day as to the specific nature of the virus of rabies and hydrophobia, than was known or imagined by the ancients. Those who have given the greatest amount of time and labor to the study of this disorder are the most cautious in pronouncing upon its appearance—the last to claim anything for its treatment.

There are those who boldly say that it is a pure neurosis. Bosquillon, in the beginning of this century, stood up alone against those who considered it to be due to a specific virus, and Lauder Lindsay and Tuke have recently shown afresh that many cases may be attributed solely to the effect of the imagination, while R. White actually inoculated himself twice from rabid dogs, to prove his opinion that there was nothing specific in the virus. On the other hand, Hertwig, Virchow, Bollinger and others in Germany, and Doleris, Bouley, Colin and others in France, have experimented and written to prove the contrary opinion. Bollinger even goes so far as to intimate that the disease may be communicated through the intervention of fleas and lice!

Thus we see that the most opposite views have been held in regard to the nature of hydrophobia. There is no authority so undisputed that it may be appealed to to decide what it actually is. Consequently there is no question which demands for its solution more skill, acumen, thoroughness, and conscientiousness, than that which presents itself when one is called upon to give a name to the congeries of symptoms sometimes seen after bites from dogs, and usually followed by death.

Only by the exercise of the greatest caution can any one hope to avoid stumbling in the darkness which invests this subject. No hasty adoption of the diagnosis of hydrophobia will do, no implicit acceptance of the stories told by patients or friends, no easy belief that one knows what are the symptoms or what should be the treatment of the disorder, if this knowledge has been gained from the ordinary text-books. If ever the mists in which this subject is now shrouded are to be dispelled, it will be by the converging light of many histories of cases, observed with the most scrupulous and intelligent care, and sifted with the most pitiless sifting.

And it should never be forgotten that the more eminent the position of one who speaks on any subject, the more injury is done to the cause of science if he makes a mistake.

"PLANTS WITHOUT EARTH."

Under the above caption, Mr. R. Heath, in *Good Words*, gives an account of the researches of Alfred Dumesnil, the "gardener of Vascœnil," as to the possibility of cultivating plants without earth. He has discovered what he calls a "fertilizing moss," in which he wraps up their roots, and it affords nourishment to all kinds of vegetable life, and for an indefinite time. His experiments have been continued for two winters, during which time his house has been a blooming parterre, while nature without was in her shroud of snow. The process

has been patented in England, and a depot for the sale of the fertilizing moss will shortly be opened.

To chronic invalids this will be welcome intelligence, as a means of beautifying their rooms and of varying the monotony of their lives, while it will afford a ready means, also, of trying the effect of plant life upon pulmonary diseases, to which especial attention has been called by Dr. J. M. Anders. It is said, also, that Dumesnil has even succeeded with the *eucalyptus globulus*, and if this be so, we may find a new means of combating malaria even in our very homes.

In the July number of the same journal, M. Dumesnil gives minute directions as to the method of procedure. He also states that strawberries may be plucked from the vines in the midst of the table, and even dwarf fruit-trees may be similarly utilized.

RE-VACCINATION.

THE value of re-vaccination has lately had strong evidence in its favor on comparing the results of differing practice in the English postal and telegraph services. Exposure is about alike in the two departments, yet the results have been startlingly different. In the postal department between ten and eleven thousand persons are employed permanently, all of whom must be re-vaccinated on admission, unless it has been done within seven years. Among all of these the last returns give but 10 cases, chiefly of varioloid, and not one fatal case.

In the telegraph service, there are but 1500 persons employed, and re-vaccination is not insisted upon. Among these occurred twelve cases, eight of them among persons not having been re-vaccinated, and one died.

REVIEWS.

PATHOLOGIE UND THERAPIE DER RACHITIS. Von DR. LUDWIG FÜRTH, Dozent an der Universität, etc. Wiener Klinik, V. and VI. Heft, Mai-Juni, 1882.

PATHOLOGY AND THERAPEUTICS OF RACHITIS. By DR. LUDWIG FÜRTH, etc.

THIS work is written upon a subject of which there are so many exemplifications in Vienna that the name, "Englische Krankheit," by which it is very often called, sounds like a fine irony.

"Every clinical description of rachitis," Dr Fürth says, "is incomplete, and, if it be held up against the picture of some case that has fallen under the observation of the reader, may but imperfectly cover it. It can only present isolated types, and indeed only those of most frequent occurrence; while again and again rachitis appears in a form possessing only isolated features of these isolated types, or even in one which does not exhibit these at all."

Then the learner may well be on his guard against error, and, bear in mind that, while continued digestive disorders are not necessarily the precursors of rickets, yet they must always be regarded with suspicion, especially if they be accompanied by free sweating on breast and head, even in apyretic intervals. Then, if the case be one of rachitis, what follows may be observed: "The child, which has already begun to walk, which so far has shown little sensitiveness under the ungentle treatment of its care-taker, now cries out on the most careful handling, the lightest grasping of the chest; it experiences pain on being set down, or having its hands taken hold of. The use of the extremities appears no longer as free as before, so that one of the earliest changes in the conduct of the child is its bad attitude; for standing erect, walking, and sitting seem uncertain. The child is anxious in its movements, it seeks all sorts of supports, walks as little as possible, preferably on hands and feet at once, appears unusually dull, and avoids every unnecessary movement; it bends and stoops to pick up any thing from the ground with great constraint and effort, in doing which it helps itself by sitting quite down on the ground and reaching after the object with outstretched hands. The child, heretofore bright, active, and never still, likes to fix itself comfortably and long in one place, because clambering up and down from the chair is an occasion of special toil and hardship. In order to avoid this, it must make peculiar movements, which are pointed out as bad habits. All these are circumstances which finally bring those about the child almost to believe that disturbances of unknown character in the locomotive apparatus of the child must be present or coming on."

But the finely drawn picture of the appearance of a rachitic child is too comprehensive to be given in its entirety; we can, in leaving it, only allude to the details of digestive disturbances, sweating, emaciation, paleness, and finally the characteristic deformity of the bones.

The author discusses the question of congenital rachitis, and doubts the accuracy of the diagnosis in so-called cases. The same doubt is expressed in regard to attacks said to originate much after the end of the third year.

Acute rachitis, an extremely rare form, he holds to have little in common with real rachitis, except the name. As Fürst has said, he believes there may be an acute prodromal stage of a genuine rachitis, but one must not confound with this non-rachitic disorders of nutrition, accompanied, though they may be, with pain and hypertrophy of the bones.

The etiology of rachitis, the author says, is far from exact, and there is no children's disease for which a precise explanation is so utterly wanting. This may be true in a sense, but it is not absolutely true. The author's own words and universal observation may be set against this assertion. The occurrence of rachitis can always be traced to imperfect nutrition, dependent upon bad hygienic surroundings and insufficient or improper food, or upon a depraved constitution incapable of taking advantage of the best surroundings and food, or upon both. Thus, in Vienna, as elsewhere, the greatest ravages of rachitis are among the poor bottle-fed children, deprived of their natural and proper sustenance, and often supplied with the most improper food.

Dr. Fürth denies absolutely the heredity of rachitis—miserable constitutions are often enough inherited, but not rachitis. Indeed, healthy parents may have rickety children, and childen of parents who have had severe rachitis may escape it.

He devotes considerable space to refuting the surprising claim of Parrot, that all cases of rachitis can be traced to hereditary syphilis, a claim which has found few acceptors. That children with syphilitic parents are sometimes rachitic, no one can deny, but that syphilis is always, or even often, the cause of rachitis any one may deny. The logical method by which Parrot arrived at his conclusion is as follows: many

children with rachitis have manifestations like those of hereditary syphilis; they are those of hereditary syphilis; rachitis is hereditary syphilis. A neat and conclusive style of argument. Unfortunately, however, for Parrot, not only are there those who see—as did the Pope in Father Tom's argument that *black* was *white*—a flaw in such logic, but as Dr. Fürth says, "the whole symptomatology of rachitis presents, in its entire course, not the remotest similarity to that of acquired or hereditary syphilis of children." Happily the habit of promiscuously attributing to syphilis otherwise inexplicable phenomena, is not as general as it once was. But it is still widespread enough to call for renewed warning and reprobation, whenever it shows itself.

The next theory Dr. Fürth refers to is that advanced by Oppenheimer, of Heidelberg, who considers rachitis to be of miasmatic origin. Of this the author speaks with a consideration which looks like partiality when we endeavor to find in Oppenheimer's argument the reason for his belief.

As to the essential nature of rachitis we find a most interesting section of Dr. Fürth's paper. Experiments as to the influence of an insufficient supply of certain elements of food, especially of lime salts and phosphorus, are quoted. These experiments are contradictory and lead the author to the conclusion that a genuine rachitis cannot be excited by artificial feeding. The only theory in regard to the immediate cause of rachitis which, in his opinion, continues to find much acceptance is the "acid-theory;" and this, he says, is losing ground of late. This view is thus stated by Seemann: "The impoverishment in lime-salts of rachitic bones is the consequence of a specific digestive disorder, consisting in a deficient production of hydrochloric acid in the stomach. This deficiency in hydrochloric acid is a consequence of the lack of chlorides, which can be procured by the free use of salts of potash." The fact is that no analysis of food, or of excreta, has furnished good reason for attributing rachitis, or freedom from it, to the influence of any one ingredient. It can be charged to poor food or poor assimilation—more precise we cannot yet be.

Of the pathological anatomy of rachitis, nothing new is stated by the author, but his description is full, scholarly and exact. A distinction is drawn between fracture and "infraction," in the latter of which only part of the circumference of a bone is broken, and that usually the convex side of distorted bones.

Of the symptomatology he says, "Craniotabes is a special symptom of rachitis in the first quarter or half year of childhood, appearing in no other disease. It is one of the first, if not almost always the very first, symptom of this disorder. Craniotabes may remain the sole symptom of rachitis, or be the precursor of others." He says that the apparent enlargement of the cranium is not actual, but relative, and depends upon the want of development of the facial bones—a statement, the absoluteness of which might be questioned. He quotes Fisher, of Boston, as having, in 1833, first called attention to the systolic head murmur, heard over the fontanelle, in rachitic children. This is, as the author says, no longer considered pathognomonic.

Of nervous phenomena, he lays great stress upon the occurrence of spasm of the glottis, which, he says, occurs in children under one year, only when they are rachitic. The older ideas as to the prejudicial influence of teething upon rachitis, he inverts into a prejudicial influence of rachitis upon teething.

In speaking of the bony changes, the author makes a mistake, we think, in passing somewhat hurriedly over those of the pelvis, on the plea that they are in the province of the obstetrician. The order of appearance of changes in the bones he puts thus: first, the protrusion of the costal cartilages or craniotabes, then swelling of the epiphyses of the radii, and afterward other changes in irregular order.

The prognosis of rachitis depends, of course, upon the condition and surroundings of a child, and, as the author says, must be the more uncertain, the younger the disease is—that is, until something can be learned by observing its progress. The first sign of improvement is improved digestion.

In the important matter of treatment, Dr. Fürth speaks clearly and positively. Vegetable food is to be avoided as much as possible—a view which is sadly confirmed by the fate of many children in Vienna. Cow's milk he holds to be the very best substitute for human. The most important difference between these two kinds is in chemical reaction, and the usual acidity of cow's milk must always be corrected. The fact that the casein of cow's milk coagulates in much larger masses than that from human milk, is mentioned; but no suggestion made as to how this may be obviated. The addition of barley water, so common in this country, is not alluded to. Dilution is spoken of, and the addition of sugar to approximate the proportion of this constituent in human milk.

As to medicament, great stress is laid upon the treatment of complications. Spasm of the larynx cannot, the author says, be treated as Flesch recommends, by letting the child lie quiet in bed. Something must be done for the credit of the physician and the comfort of the patients. Chloroform and electricity are useless or inapplicable; long-continued administration of bromide of potassium is the most useful plan to pursue, according to his experience.

Cod-liver oil is the best systemic remedy for rachitis; its only contraindication is severe diarrhœa or gastric catarrh. It should never be given on an empty stomach, and the author disguises its taste with syrup of orange, or anise or fennel. He considers the brown, unclarified cod-liver oil as the most suitable. He states particularly that the benefit derived from cod-liver oil is not due to its contained iodine.

Phosphate of lime holds no high place in the author's estimation. Phosphorus, he says, "has entirely disappeared from the practice of our times—the present Austrian Pharmacopœia no longer contains it." Iron, on the contrary, he thinks a valuable tonic. Warm and medicated baths are also useful, especially salt baths. Simple change of air, he says, sometimes produces remarkable improvement in rachitic children.

The last part of the treatment of rachitis, which the author considers, is the orthopædic and surgical. As to the former, he suggests common sense avoidance of whatever is calculated to cause or increase deformity, and speaks very approvingly of Sayre's plaster jacket. Surgical interference must never, he sensibly remarks, be dissociated from proper medicinal and dietetic treatment.

So much in outline of the author's views. Of criticism, there is little to be made. So thoroughly and so admirably has he presented the subject that we rise from our examination of his work with a sense of its value, which brings a regret that it is not accessible to readers unfamiliar with the language in which it is written.

One little drawback to its mechanical construction is the fact that, like not a few other German monographs, it is not adequately divided into chapters and sections. If this were done, and done judiciously, it would be a great help to the reader, both in his first study and in subsequent reference to it.

CORRESPONDENCE.

BRITISH MEDICAL ASSOCIATION—JUBILEE MEETING AT WORCESTER.

WORCESTER, August 12, 1882.

IN continuation of my last letter, I must take up my account of the proceedings on Thursday, August 10. At the general meeting held that evening, Prof. Stokes, of Dublin, gave a very earnest and eloquent *Address in Surgery*. He said that the Association, as it had its birth in the "Faithful City," so it had proved faithful in many good and noble ways—faithful in removing professional jealousies and softening asperities—faithful in protecting with its broad and strong shield those who had been cruelly and unjustly attacked—faithful in its efforts to raise the social status of the profession—faithful in its attempts to extricate public opinion from the quagmires of sentimentalism and folly—faithful in aiding and encouraging the scientific vanguard of the profession. The list of advances in surgery during the last half century was a goodly one. Among these were the abandonment of an indiscriminate bloodletting in almost every form of acute disease, of a reckless use of mercury in the treatment of certain diseases, and of setons and moxæ in hopelessly irremediable articular and other diseases. Having enumerated a goodly list of the modern improvements in surgical treatment, he singled out, as topics which far surpassed in importance all others, the three "giant strides that the past half century has witnessed,"—namely, the discovery and application of anæsthetics, the restoration of diseased or injured bones and joints necessitating resection, and "the enunciation of the principle and establishment of the practice by Pasteur and Lister of antisepticism in the treatment of wounds." Such advances may well make us feel a pardonable pride in British surgery, and give confidence in the coming triumphs of our art. As to anæsthetics, he adverted to the peril which must necessarily attend their administration, and the need for caution and the adoption of such a rule as that formulated by Mr. Hutchinson in reference to the use of chloroform in cases below six and above sixty years of age. He expressed a personal preference for ether, as economizing time, as being safer, and, as a rule, being followed by less sickness and a slower return to sensibility. The best methods for administering it were those in which the air is rebreathed by the patient, and experience had not confirmed the *à priori* belief that this admixture of ether vapor and carbonic acid gas introduced an additional element of danger. After briefly enumerating the advantages of anæsthetics, and referring to Morton's priority in their application to surgical practice, he passed to the subject of antiseptic surgery, in support of which he spoke in terms of considerable force and eloquence. Naturally he referred to the address delivered by Mr. Savory at the Association meeting at Cork, in 1879, where the subject had been adversely handled, and declared that when "the address is stripped of all its brilliant eloquence and rhetorical decoration," it reveals the admission of the germ theory of putrefaction, and the fact that the method of dressing employed by Mr. Savory is essentially antiseptic. Mr. Lister's recent utterances upon the value of the carbolic spray had been much misunderstood; for he did not abandon the antiseptic principles, but looked forward to obtaining more perfect means than the carbolic spray afforded. The various views of the nature of inflammation propounded by Burdon Sanderson, Ogston, and Hueter, as to whether the infective properties of inflammatory products are or are not primarily dependent on the contact of atmospheric organisms, were shown to be equally consonant with the prophylactic principle of antiseptic surgery. The weak point of the "persistent and obstinate opposition" to Listerism is the general admission of the truth of the germ theory of putrefaction; whilst Mr. Lawson Tait's "dead tissue factor" was regarded as a superfluity. "Those who advocate and practise what they are pleased to term a "modified" antiseptic system, attempt, in fact, in a roundabout, clumsy, inefficient way, to do precisely what those who practise Listerism achieve by means which are the outcome of accurate scientific research. The aim in both cases is to neutralize or destroy the agencies which predispose to and produce the *materies septica;* in the one instance by numerous uncertain and often inefficient methods, and in the other by the unerring artillery of chemical agency." Mr. Stokes disposed of the taunt that Listerism lacked originality by mentioning what he had himself seen of Maisonneuve's practice. He considered that ovariotomy was not the best test of the efficacy of the method; one of the best tests of its value is resection of the knee-joint; and he illustrated this from his own experience. He also related other remarkable instances of "antiseptic triumphs," and asked whether such results could have been obtained previous to Listerian teachings. There can be but one reply—impossible. As to its hygienic effects, he mentioned the change that had been wrought in mortality from erysipelas, pyæmia, and hospital gangrene in the hospital to which he is attached—when its present condition is contrasted with that which prevailed during his studentship, an experience which has been so widely repeated abroad. Mr. Stokes then defended Professor Lister and his followers for not having more recourse to statistics in demonstrating the superiority of antiseptic methods, and asked why Mr. Savory made no mention of ovariotomy when he gave the statistics of operations at St. Bartholomew's Hospital. Without himself regarding statistics with the reverential awe of some, he mentioned that at the Richmond Surgical Hospital in 600 operations performed by himself and colleagues during the past three years, the mortality was 3.6 per cent.; "and there was not a single case in which Listerism was accurately employed that was followed by any infectious disease." He enumerated some of the directions in which owing to antiseptics the field of surgery had been widened, and severely commented on the line taken by those who wilfully refuse to acknowledge its benefits, and concluded his remarks on this head as follows: "In the interest and for the credit of British surgery it is time so unrighteous a warfare should cease. It is time that the irritating dust of an unreasoning prejudice should be swept away. It is time that one of the greatest discoveries and boons to surgery this century has produced should be universally recognized as such. It is time that its discoverer and exponent should be acknowledged as one of whom it may well be said—

> "With genius Nature joins in everlasting covenant still,
> The promises of one, the other fails not to fulfil."

In the third part of his address Mr. Stokes dealt with the method adopted for bringing about a regeneration of bones and joints necessitating resection on account of injury or disease, with which the names of Syme, Langenbeck, and Ollier must for ever be associated. He described the conditions under which these operations were most successful, and referred to the great advance made by the introduction of bone-transplantation by Dr. McEwen of Glasgow. Then, speaking more particularly of bone-resection, he urged its performance before any profound organic changes take place. A reference to amputation, and especially to the single flap operation of the late Mr. Carden, of Worcester, closed this survey of surgery, and the rest of the address was occupied by an eloquent vindication of experimental research, and a protest against the increas-

ing agitation that is now maintained in opposition to it. He concluded: "I have mentioned many achievements in surgery the past half century has witnessed. Fifty years hence this great Association will, I hope, again meet here to celebrate its centenary; and my successor will, I trust, with greater ability and eloquence than I can command, tell of as great or greater triumphs than I have done. To enable him to do so we can all aid, some powerfully, others feebly; but still every unit in this great brotherhood can assist; and it should be our ambition as well as our prayer, that when the hour arrives for us to cease from our work, we may all feel, on looking back on our lives, that we have done something to that end. Something—be it great or small—in the interests of our common humanity, in the interests of our loved country, and of a pure devotion to truth, to render the science to which we have devoted our lives nobler and fairer than before."

At the close of the Address on Surgery, the Stewart Prize of 50 guineas was presented to Dr. Vandyke Carter, for his researches on spirillum fever.

The Annual Dinner of the Association, attended by about two hundred members, was held in the evening.

The concluding General Meeting was held next morning, when, in addition to the various complimentary votes, there was a very lively discussion on the question of the *Notification of Infectious Diseases*. This had already been debated in the Section of Public Medicine, but it was determined to take a vote at the general meeting. There is a scheme on foot to make the notification of every case of infectious disease, to the local sanitary authority, compulsory. It has been suggested to throw the onus, and, I may add, odium, of carrying out this scheme on the doctor in attendance. This was warmly debated, and a very general expression of opinion in favor of the general scheme, but making the householder the person responsible for giving the notice, was elicited. I am sure your readers will fully appreciate the objections that may be fairly urged to the original proposition.

The Middlemore Prize of 60 guineas was presented to Mr. Adams Frost, for his Researches in Ophthalmic Surgery.

Reports of various committees were received. This brought the work of the meeting to a close, and excursions and entertainments became the order of the day. Many visited the famed brine baths of Droitwich. In the afternoon the whole Association was received by Earl and Countess Beauchamp, at their seat, Madresfield Court, Great Malvern.

In the evening, the President of the Association, Wm. Hastings, M.P., the son of the founder of the Association, gave a musical *soirée* to the Association in the Shire Hall. Saturday was devoted to excursions to Malvern, Hereford, the Wye, Stratford-on-Avon, and other places of interest in the neighborhood. The meeting was a very pleasant one, but perhaps hardly rose to the occasion of a jubilee. There was a conspicuous absence of London members, probably owing to the exhausting effects of the Congress of last year.

At the second session of the SURGICAL SECTION two important subjects were the main topics of discussion—the surgery of arteries and abdominal surgery.

Mr. Bryant related a case of *Double Popliteal Aneurism*, of which one was cured by pressure, and the other by Speir's artery constrictor with antiseptic (not aseptic) precautions.

Mr. Thomson related the history of his case of *Ligature of the Innominate Artery for Subclavian Aneurism*, and showed the specimen. Subsequent speakers were quite agreed that the fatal result was not dependent upon the ligature of the artery, but was due to ulceration of the drainage-tube sinus, probably opening up the vertebral artery; the ligature (ox aorta) had acted perfectly. The experience of this case was held to be encouraging, but it left it an open question whether in another case it would not be well to ligature the vertebral artery at the same time as the innominate, even if not the common carotid artery as well.

Mr. A. H. Dolman reported a case of *Traumatic Axillary Aneurism* successfully treated by ligature of the subclavian artery. So much difficulty was met with in getting the thread around the artery (the left), that the clavicle was divided to expose the vessel.

Mr. Barwell showed the Aneurism Needle he had had made for cases of this kind, and expressed his belief that had it been employed division of the bone would have been unnecessary.

Mr. Bartleet read a paper on five cases of *Ligature of Large Arteries*. One was a case of femoral aneurism, for which he tied the common femoral trunk with chromic catgut; the wound did not remain aseptic, and secondary hemorrhage came on. The wound was then opened up, when it was found that the artery had separated one-tenth of an inch above the ligature. The two ends of the vessel were then tied with a hempen thread. Again there was repeated secondary hemorrhage, for which the external iliac artery was ligatured with whipcord, with a final successful result. This case presented many features of great interest from a practical point of view, and would in itself have afforded ample material for a good discussion.

Mr. Bennett May related a case of *Ligature of the External Iliac Artery* and discussed the best material for ligatures, and stated that there was more difficulty in getting primary union of a wound when chromic catgut was used than when carbolic gut was employed, and he expressed his preference for common catgut soaked for a long while in carbolic oil.

Mr. Robson showed an *apparatus for obtaining an antiseptic atmosphere to replace the carbolic acid spray in surgical operations*. Asserting that while the carbolic acid spray was aseptic, it was not antiseptic, and was also harmful, Mr. Robson advocated the value of an antiseptic, dry, non-poisonous atmosphere. This he obtains by pumping air through cotton-wool to purify it from all suspended impurities, and then through eucalyptus oil. To show the antiseptic value of an atmosphere of this kind, he had taken several large, wide-mouthed glass jars and poured a little of this oil into each, and had then suspended jars of sterilized hay infusion in them, and had removed their cotton caps for various periods, and in every instance, except one, bacteria had not subsequently developed in the infusion. He had also used it for surgical purposes, and Mr. Spencer Wells had used it during the excision of a mamma, and had expressed himself pleased with it.

Mr. George Elder related a successful case of *Nephrotomy and Nephrectomy* for scrofulous pyelitis.

Mr. Lawson Tait showed a girl from whom he had excised a kidney through the linea alba, and he also showed the kidney, which was sacculated, and contained a large calculus.

Dr. Cullingworth related a case of *Nephrectomy for Hydronephrosis* by abdominal section, in which the patient died from shock twelve hours after the operation; and in reference to this case Mr. Tait remarked that he should never attempt nephrectomy for renal cysts, as the operation of incising and draining these cysts, proved so successful in his hands.

Mr. Lawson Tait recorded a third successful case of *Cholecystotomy*, and showed a large number of gall-stones he had removed from the gall-bladder. The gall-bladder formed a prominent abdominal tumor, and it was an interesting feature of the case that, although the cystic duct was completely obstructed, there had not at any time been jaundice. He opened

the gall-bladder, and stitched the edges of the wound in it to the abdominal incision, and extracted a large number of stones. The discharge had continued mucous until that week, when bile had made its appearance, showing that the duct had become patent again. Mr. Tait therefore intended to freshen the wound, and close the sinus.

Mr. Lawson Tait then read a paper on *100 Consecutive Cases of Ovariotomy* performed during the last thirteen or fourteen months, and in which he had not used any kind of antiseptic measure. Of these three patients died, one from choking during vomiting, and two from venous thrombosis starting at the pedicle and spreading quite up to the heart. Six of the patients were pregnant at the time of operation, one in addition had acute peritonitis, one of them miscarried, all got well, and five were delivered of living children at term. Four patients had acute peritonitis at the time of operation, and all recovered. In two the tumor was solid fibroma of the left ovary, in ninety-eight it was cystoma, of these eleven were parovarian cysts, sixty were cysts of one ovary only, and among these were the three deaths, and twenty-seven were cysts of both ovaries. In fifty-three cases there were serious adhesions, but he had not found that this factor in any way added to the mortality. Of the three fatal cases there were no adhesions in two, and slight parietal adhesions in the third. In seventeen cases the tumor was sessile. All these cases were dressed with dry absorbent cotton-wool; in about one-twentieth of the cases a part of the wound opened, and then it was dressed with zinc ointment or red lotion. Mr. Tait attributed his improved mortality: (1) To the total abandonment of Mr. Spencer Wells' clamp; (2) to the thorough cleansing of the peritoneum, as recommended by Keith; (3) to the draining of the peritoneum, as recommended by Keith; (4) to increased personal experience; (5) to the diminished number of cases which had been previously tapped; those (two) of his patients who had died from thrombosis had been tapped, one sixteen and the other thirty times. He believed that if tapping was never adopted there would be no mortality except from tetanus and similar outstanding risks; (6) the complete abandonment of antiseptic treatment; (7) the establishment of hospital discipline and hygiene; this he deemed of so much importance that in only exceptional circumstances would he consent to operate in private houses.

Dr. Ward Cousins said that one danger of tapping was rotation of the pedicle on itself.

Mr. Coates (Salisbury) said that it was very difficult to harmonize Mr. Tait's statements with those of Dr. Stokes earlier in the day in reference to *antiseptics*. But his experience in general surgery was that while before his adoption of the Listerian treatment he did not obtain primary union of wounds in one per cent. of his cases, since that adoption he obtained it in every case. He incidentally mentioned a case of a very large splenic tumor, in which he was urgently requested to do, at any rate, an exploratory operation. On opening the belly and passing in his hand he found a large number of soft very vascular adhesions between the tumor and the abdominal wall, in tearing through which there was very free hemorrhage; when this had ceased he closed the wound. The patient recovered, and from that time the tumor rapidly shrank in size.

Mr. Thomson referred to the great diminution in the mortality of his cases that Mr. Tait observed when he first adopted the antiseptic treatment, and maintained that the results of general surgery abundantly proved the value of this treatment.

Dr. Bantock, in opposition to Mr. Tait, maintained that adhesions of ovarian tumors to intestine and pelvic organs are serious complications of ovariotomy. He had given up antiseptics, and he had not had more septicæmia than other operators who had used it, and he asserted that Listerism had not freed us from septicæmia.

Dr. Sutton (Pittsburg) had spent a considerable period in studying European surgery, and he stated that in Berlin, Vienna, Halle, Kiel, and Leipsig he found antiseptics everywhere, and such results that on coming to England he dared not have opened the abdomen without employing antiseptics; but then he went to see Keith's practice, and his views were changed; for Dr. Keith and his son (who had done five cases) had had a run of fifty cases of ovariotomy with only one death; and he had Dr. Keith's authority for stating that he had never used the carbolic spray stronger than was recommended by Prof. Lister. He had also seen Mr. Tait's practice for three or four weeks, and he had been very careful to watch his practice closely; for he had been told that he was a man who did not speak the truth; but he had only seen one of his wounds in which there was a drop of pus—one already mentioned by Mr. Tait. In America antiseptic surgery had many friends in the East, but had not made much headway out West; and since the International Congress all American surgeons were waiting to see what the English surgeons would make of this question.

Dr. Ed. Taylor, who was for some years Mr. Spence's assistant, said that the question was one of careless surgery *versus* first-rate surgery. Listerism was but a cover for careless surgery, the results of which had been equalled by Mr. Spence's first-rate surgery.

Mr. Tait, in reply, said that the unfair treatment he had received in London had reached such a point that he had had to threaten one gentleman with an action for libel. He advocated placing the operation of ovariotomy in the hands of a few surgeons only. In reference to the question of antiseptic surgery, he stated that he found one great argument against it in the constant changes which were being introduced into it. One preparation was always being abandoned in favor of another; the original catgut ligature was replaced by the chromic gut; and a new method of preparing the latter was recently introduced. If the practice were as perfect as had been represented, it would not need such constant modifications.

The last meeting of the section was mainly taken up with a discussion on *bone-setting*, which was opened by Mr. Howard Marsh, who referred to the cases benefited by "bone-setters;" and urged that these should be taken in hand with more boldness by surgeons, while many cases of stiff joints should be prevented by more judicious treatment.

Mr. W. Adams followed with a paper on the same subject, in which he attempted to classify the cases which would be benefited by forcible movement; and he urged that the treatment should be gradual and prolonged, rather than rapid.

Mr. Dacre Fox, who had assisted one of the family of Taylors, for many years "bone-setters," gave a very interesting account of the work of the firm. He said that in his experience "bone-setting" consisted largely in the treatment of recent fractures and sprains, and to only a limited extent in stiff joints. He urged surgeons to take more pains in the treatment of sprains, strains, and other apparently minor and simple injuries, which, if neglected, were often attended with grave inconveniences.

Mr. Pearce Gould, referring to cases in which the adhesions were mainly, if not entirely, extra-articular, said that it was of importance to break down all the adhesions at once, and then to persevere with passive movement to the full extent daily, and gradually bring up the nutrition of the wasted, disused muscles, by ac-

tive movements; perseverance on the part of surgeon and patient was very necessary.

At the first session of the SECTION OF OPHTHALMOLOGY, a discussion on the *Extraction of Senile Cataract in its Capsule* was opened by Dr. Edwyn Andrew, who described new instruments to separate the lens in its capsule, by tearing through the suspensory ligament. To obviate all pressure upon the globe during the operation, he has discarded all forms of speculum, and instead he passes a thread of catgut through one or both eyelids, and by it has the lid or lids held apart and away from the globe. Dr. Andrew advocated a more frequent resort to this operation. The general opinion elicited was, that this mode of cataract extraction is good in over-ripe cataract, and that it is easier to perform the older the patient, owing to the lessened resistance of the suspensory ligament in old age. In connection with this latter point, Mr. Priestley Smith stated the interesting fact that, having experimented on the extraction of the lens and capsule on the dead body in many cases, he had found it was much easier to do it in the corpses of aged persons. Mr. C. Macnamara, whose name is associated with this operation, and who has had a large experience of it, stated that he prefers it to any other in properly selected cases, and particularly in old people.

Next day Mr. Anderson Critchett read a paper on the *Treatment of Lamellar Cataract*, in which he advocated, in preference to removal of the lens, the formation of an artificial pupil by Tyrrell's hook.

Dr. Arthur Benson followed with a paper on the *Treatment of Partial Trichiasis*. The plan Mr. Benson recommends is to thrust one pole of an electrolytic machine into the eyelid, towards, or, if possible, into the erring hair-follicle, and to place the other pole on the forehead. The object is to destroy the hair-follicle, and the treatment is continued until the eyelash comes out easily with the root-sheath attached.

Mr. Nettleship and Mr. Priestley Smith related three cases of *Atrophy of the Optic Nerve*, followed by continuous dropping of watery fluid from the nose. The fluid possessed negative characters, and was not cerebro-spinal. In one of the cases there was evidence of a growth in the nose, and in another the nasal mucous membrane was thickened and excoriated, but whether as the cause or the result of the discharge was not known. In one case there were also curious nervous symptoms, drowsiness, and stupor, when the flow temporarily ceased; and during one of these attacks the patient died, but an autopsy was not obtained.

Mr. Priestley Smith showed at this meeting a *new registering perimeter*, which had the merits of simple construction and inexpensiveness.

Mr. Nettleship opened a discussion on the *Value of Eye Symptoms in the Localization of Brain Disease*. The principle points alluded to were uniocular papillitis, with evidence of intracranial disease; optic-atrophy, especially in relation to color-blindness; hemianopsia, and the recently recorded cases of hemiachromatopsia, the author thinking it probable that, in most cases of hemianopsia, the lesion is higher up than the optic tract; cerebral amaurosis from lesion of the occipital lobes; ocular paralyses, peripheral, nuclear, and cortical. Attention was called to several other conditions bearing more or less closely on the subject—*e. g.*, "pseudo-glioma," with brain symptoms, recoverable infantile amaurosis, hydrocephalic choroiditis, megrim, complicated herpes of cranial nerves, and others. A short discussion followed, in which Dr. Edwyn Andrew, Dr. Hughlings Jackson, and Mr. Priestley Smith took part.

At the first meeting of the SECTION OF PATHOLOGY, Dr. Stephen Mackenzie opened a discussion on *Diabetes*. He specially referred to the cause of death in diabetes, and the nature of diabetic coma, which he discussed, maintaining that it was complex, in the majority of cases being due to acetonæmia, and in only a small proportion of cases due to fat embolism. He agreed with others in believing this coma to be most common in young subjects. The statistics of the London Hospital were quoted to show the relative frequency of the various complications of diabetes. Dr. Saundby stated that although he had carefully looked for it he had not often succeeded in demonstrating fat embolism in death from diabetic coma. Dr. Shingleton Smith contended for the nervous origin of diabetes; and as one piece of evidence related a case of tumor in the cervical region of the spinal cord, which was accompanied with glycosuria.

At the same meeting Mr. Jonathan Hutchinson opened a discussion on the *etiology of tumors*, in which he insisted on their local origin, and dwelt particularly upon rodent ulcer and the precancerous stage of disease. Sir James Paget contended for the dual origin of malignant tumors, constitutional tendency, and local change. Mr. Butlin gave an excellent demonstration of the microscopical appearances of the chief forms of tumors. Dr. Thin showed some hairs in which trichophyton tonsurans had been artificially cultivated; and Mr. Abraham gave a very interesting demonstration of granulation tissue in a sponge network as obtained in the new process of sponge-grafting.

The closing meeting was opened by an exhaustive paper on *Rodent Ulcer* by Dr. Sangster, in which he clearly established the fact that the disease is not primarily connected with the sweat-glands. but that the morbid change starts from the Malpighian layer and outer sheath of the hair-follicles. Dr. Thin disputed this view.

The rest of the morning was occupied with a demonstration of various forms of *bacilli*, which excited a good deal of interest, and was one of the most successful events of the meeting. Dr. Heron showed Ehrlich's process of preparing tnbercle bacillus, and he was followed by Dr. Gibbes, who demonstrated his process of preparing the same bacilli, which has already been described in THE MEDICAL NEWS (Aug. 19), and it was very evident that this process, while decidedly simpler than Ehrlich's, is also more effective, and is, therefore, more useful. Dr. S. Mackenzie also showed a specimen of tubercle bacillus prepared by Goltdammer's method.

In the SECTION OF OBSTETRIC MEDICINE, Dr. Bantock read a paper on his cases of *Hysterectomy*, and in the subsequent discussion, Drs. J. Williams and Wallace strongly deprecated a frequent resort to this operation, asserting that the cases justifying it were but very few.

Dr. Edis gave a *précis* of the rational treatment for Menorrhagia, and Dr. C. H. Routh described a form of Dysmenorrhœa associated with Gonorrhœa.

The second meeting was entirely taken up by a discussion on *Subinvolution of the Uterus*, its causes, its relation to uterine disease, and its preventive treatment, which was opened by a paper by Dr. John Williams. He referred to the various methods for determining the progress of the involution of the uterus after delivery, to the work of Heschl, Dupaul, Sudukoff, Melson, aud Sinclair. The uterus disappeared into the pelvis on or before the twelfth day after delivery, if involution goes on healthily. Taking this as a standard, Dr. Williams found, from the study of 113 cases, that the causes of involution are post-partum hemorrhage, retention of portions of placenta or membranes, lacerations of the perineum, pelvic inflammations and fever during the lying-in period. Lacerations of the cervix do not appear to give rise to it. Subinvolution causes menorrhagia, dysmenorrhœa, and prolapsus. The pelvic in-

flammations so frequently associated with it are not its results. Its peculiar treatment consists in completely emptying the uterus after delivery, maintaining an efficient contraction of the organ, and in preventing fever. The best means of securing the last two are the frequent use of hot disinfecting vaginal injections, and perfect closure of tears of the vaginal orifice.

In the SECTION ON MEDICINE, Dr. Austin Flint read an able paper on the *Self-limited Duration of Pulmonary Disease*, and advocated the employment of the binaural stethoscope.

Dr. Balfour opened a discussion on Chlorotic Murmurs. Dr. C. T. Williams spoke on the Contagious Nature of Phthisis. On the last day, Dr. Leech opened a discussion on the Treatment of Cardiac, Hepatic, and Renal Dropsy.

STUDIES IN THE BERLIN GESUNDHEITS-AMT.

The Detection of the Bacillus Tuberculosis—The Investigation of Air, Water, and Soil.

GENEVA, August 12, 1882.

THE proverbial circumstances which alter cases, dispose as freely of the location of individuals, and so your correspondent found himself transposed from Berlin to Rome, and from Rome to Geneva, where alone there has been time offered for further communication. Everywhere over the face of the earth it was plain to see how hard is the struggle for existence among the children of men, and how oblivious the most of them become to anything but the wants of daily life. The struggle in politics which is just as bitter everywhere here as with us, is only another phase of this engrossing subject, and everywhere there is this struggle between those who have the power, including the means of subsistence, and those who have it not. Liberals and conservatives are the party names all over the old country, except in Rome. But in Rome it runs liberals and clericals, which latter party has, by the way, just suffered a general defeat.

These truly philosophic reflections would be out of place in a medical journal, were they not suggested by the observation that the same divisions obtain in the medical world, and that physicians, too, like other men, group themselves under the classes of conservatives and radicals, as regards every new discovery. The question is, not so much is the discovery true, but does it accord with preconceptions? So that it is useless to write the opinions of the so-called leading authorities. The truth is, that very few observers, indeed, are competent to give an opinion upon any subject connected with micro-organisms. And they who are competent are the most reticent, until they have subjected the question to individual study. I heard Dr. Koch one day deeply deplore the *laicisation*, if I may use the French term of his discovery, as something premature. "Such things require time," were his exact words, to be worked up by many observers from many different standpoints, and this whole method of investigation is not intended in any way to substitute or supplant, but to take its place modestly beside the other well-known and long-established lines of study, out of which it grew. The "newspaper notoriety" is a matter of regret, I happen to know, to the author of this new means of study, and it is a great injustice on the part of medical editors to attribute anything of it to Dr. Koch. A more modest, unpretentious, patient, plodding, worker, reverencing his profession, and his predecessors in it, seeking nothing but the truth, it has never been my fortune to have met.

But after all, what are these but trivialties to the question itself? Is it true? And how essential it is, if true, that it, with every detail, be immediately spread abroad, that every one who is competent may verify it, and utilize it for himself.

And let not the beginner be discouraged by failures in his first attempt. If the recognition of the bacillus tuberculosis, to confine ourselves for the present to this most important question, had been an easy task, it would have been discovered long ago. I have heard enough to know that if all the researches made in the Berlin laboratory alone could be published, it would make a contribution that would be a monument to the patience and persistence of mankind. There was the great advantage in the study of tuberculosis, over nearly every other one of the acute infectious maladies, that it is a disease which is common to most of the lower animals as well as to man; common to all in very much the same form, and of how very few of the other common infectious diseases could this be said? Consequently there was no limit to the field of experimentation. The first results were reached, however, by a process that was almost painful in the exercise of patience it required. Moreover the slightest flaw in the process would easily nullify the result. No sooner, however, had the essence of the disease been recognized than improvements began to show themselves at once in the technique of the process. So, for instance, it was soon found that the coloring solutions of Ehrlich saved a very great amount of time, and, in fact, these solutions are now in common use, in the detection of the bacillus tuberculosis. But a mere knowledge of this fact will not enable the beginner to find the objects he seeks. He must know the exact proportions in which these solutions are to be used. Thus to the saturated solution of aniline oil one hundred grammes by weight, he must add of the coloring matter solution (both fully described on previous occasions) eleven grammes. Such a nicety of combination might seem what Mr. Johnson would call "a scrupulosity," but long experience has shown that these are precisely the proportions which give the best results. This constitutes the first color, and if the exact proportion was not specified before, it was because its author had not yet made it public, a bar which is now removed. The specimen prepared, as thoroughly detailed in previous letters, is now treated to the decolorizing agents, and the subsequent staining with the aqueous solution of vesuvin, steps which I described with the utmost possible minuteness in my previous letters.

And when the specimen is thoroughly prepared, the next step is the instrument itself. A common microscope will not easily disclose the bacillus tuberculosis. It is done with the common lens every day, but by no means with the ease or distinctness shown under the new improvements. The microscope should possess the Abbé illumination apparatus, which is a series of lenses under the stage, and be provided with the oil immersion lens. The use of the oil immersion lens is just as simple as the ordinary lens, the difference being that with the former a drop of the oil of cedar is let fall upon the cover glass and the lens enters it in bringing the object to a proper focus. Then in the use of the color tests, that is, in the recognition of color and not of structure, the diaphragm is not used at all. I have written all these points with perhaps superfluous minuteness, in order to put the study of the subject in the hands of the beginner.

But besides all these preparations of the specimen, and besides the possession of the best possible instrument, there is another requisite which is a *sine qua non*. There must be an eye at the other end of the microscope which can distinguish what it sees. Right here, I may say, however, that very little practice will enable any one to recognize the bacillus tuberculosis. Because it is not the fine question of structure, but the gross question of color. A violet or a blue body in a clear brown field is such a very distinct object that a few observations will soon pick it out. Any body who can

recognize a blood corpuscle can recognize the bacillus tuberculosis, although it is rod-shaped of course, and not round, and is but about one-fourth the size of a blood corpuscle. But it is not so much the shape or structure, I may repeat again, as the color, which will at once strike the eye. Let the student recognize the presence of it first, and he can soon work out its characteristics later.

I began this letter with the intention of describing the means of analyzing the air, water, and soil which are adopted in Berlin in the detection of bacteria, micrococci, and bacilli, which elude any other means of observation. These investigatjons are full of promise in the study of the etiology of all the acute infections, and have already yielded the very important conclusion, that it is the air, and not so much the water or the soil, which chiefly contains and distributes the pathogenic organisms.

Many new improvements have been introduced in the study of the mycology of the air, the chief of which consists in the use of a long glass cylinder drawn to a very narrow tube at one end and covered with a rubber shield at the other.

The air of a given locality is drawn through the cylinder by a pair of bellows. The cylinder rests horizontally, of course, and it contains along its canal a layer of the sterilized gelatine mixture, which is poured in hot and solidifies in cooling. A given quantity of air having been drawn, as stated, through the tube, the rubber shield is attached to one end, and the other open narrow end is closed by a plug of sterilized cotton. In the course of twenty-four hours the germs begin to show up on the surface of the gelatine in the form of the well-known opacities, "vegetable moulds," which first appear in isolated spots, to gradually increase in size, and finally coalesce. Before this coalescence, however, a fragment may be removed from any opacity and studied under the microscope, where its character as micrococcus, bacilius, or simple *pilze* may be readily recognized. Quite a picturesque appearance these tubes present at a certain stage of development of the germs, spotted and dotted as is the surface, and sometimes the depths of the gelatine culture substance. Of course, in a day or two longer, the spots coalesce, the gelatine is fluidified, decomposed, and further observation rendered *nil*. But this process is easily retarded by placing the cylinders in an ice-chest. It is always seen that the number of germs is greatest at or near the entrance into the cylinder, that is, that the germs begin to fall at once upon the surface of the culture substance, to become fewer and fewer towards the rubber or bellows end. But isolated germs are carried completely up to the bellows end, as is seen by their development into patches or opacities in the course of a few days. The number of these opacities in the whole cylinder gives of itself a coarse idea of the purity or impurity of the air, and the examination of them under the microscope reveals their precise character.

In the examination of water and soil, resort is had to a different procedure. The culture substance is poured upon glass slides, where it solidifies. The gelatine is now inoculated, if I may use the term, with the water on the earth, and a number of the slides are banked up so that each is separate, of course, and the whole bank, containing perhaps twenty slides, each of which has three inoculations, is placed in the moist chamber described in the treatment of the potato. Here, too, in the course of twenty to thirty hours the opacities begin to present flocculi, as it were, which gradually increase in size. Often enough the "flocculi" are seen under examination by the microscope to be composed of several kinds of micrococci and bacilli, or are commingled with the common vegetable *pilze*. Then all that is necessary to get a variety pure is to reinoculate from the purest place another set of slides, and thus to finally arrive at the isolation of individual germs.

One of the most important conclusions reached by this means of study, was the discovery of the fact that the upper layers of the soil are always rich in bacteria and bacilli, while micrococci are present in much less degree. With reference to this interesting point, I may as well quote literally from Dr. Koch's report to the Health Office some time ago.

"Samples of soil from very filthy places, for instance, from accumulations of manure, showed an excess of micrococci, with the presence also of the vegetable fungi (schimmel pilze), but this is always only a local phenomenon. On the other hand, the upper layers of cultivated soil (horticulture and agriculture) show constantly and in great quantity the presence of bacilli. Such organisms were found in the soil of the garden of the veterinary school at Berlin just as abundantly as in the earth of a long-disused burial ground, or as in samples of soil taken from fields and gardens far removed from inhabited places." The author goes on to state that when these samples of earth are allowed to dry, the few micrococci present disappear in the culture substance, but the bacilli remain just as abundantly as before the desiccation. Hence it is concluded that the micrococci soon perish when dry, while the bacilli in the form of spores still remain alive. And this view is confirmed by the fact, as proven by experiments with disinfection by heat, that the germs of bacilli withstand a degree of heat which is fatal to the maturer forms. The author considers it probable that these bacilli spores do not spring up in the earth where they are found, but that they are wafted thither from distant products of decomposition, or are carried over in the dust of the air. It was by means of these investigations that the author arrived, also, at the very curious fact that all micro-organisms, however abundant on the surface of the earth, gradually diminish in its depths, so that at the short distance of one metre (40 inches) the earth is almost free. Even in the middle of Berlin samples of earth at the depth of one metre were entirely free from bacteria or bacilli, and showed upon the surface of the gelatine culture substance but very few scattered colonies of the smallest micrococci.

As to these terms, bacteria, bacilli, and micrococci, I may say that the lines drawn in Berlin are rather arbitrary. At least this is the case with reference to bacterium and bacillus. Of course, the micrococcus is always round and is always small, though different species vary much in size. The bacterium is a sort of transition stage between the micrococcus and bacillus, that is, it is, let us say, egg-shaped or elliptical. Whereas the bacillus is always the little rod. These are the gross differences as regards size and shape that are coming more and more into use in the description or differentiation of micro-organisms.

But this means of investigation is by no means limited to the air, the water, and the soil. It has a range which is almost infinite in extent. The author himself has suggested, and some of his co-workers have undertaken, the study of various articles of commerce (money, for instance) and of food. Milk offers a field of study by itself, and the mysteries of meat (sausage) poisoning, not due to trichinosis, may be made to display themselves upon the little surface of these gelatine slides.

J. T. W.

NEWS ITEMS.

THE BILLS FOR ATTENDANCE ON PRESIDENT GARFIELD.—A Washington dispatch to the Philadelphia *Times*, says that

"Drs. Bliss and Reyburn have at last filed their

claims before the Board of Audit, designated by Congress to settle claims for expenses incurred during the illness and death of the late President Garfield. The former desires $25,000 for his services, and the latter $10,000, which, if allowed, would exhaust the amount to be paid for medical attendance. It was originally proposed to appropriate $75,000, to cover all the expenses, but the Senate reduced the amount to $57,500, which was concurred in finally by the House. Of this, $35,000 was to be distributed among the medical attendants, and the remainder among such other claimants as might present satisfactory evidence in support of the demands.

"Before filing his claim before the Board of Audit, Dr. Bliss notified Drs. Agnew and Hamilton that he intended to ask for $25,000, and requested to be informed as to their demands. Neither of these gentlemen has replied, but it is understood that their claims will be for $15,000 each. Dr. Reyburn in his bill claims compensation at the rate of one hundred dollars per day for sixty-seven days, and a like amount for the alternate nights spent at the late President's bedside. Dr. Boynton and Mrs. Edson are not recognized by the attending physicians in any other light than nurses, although Dr. Agnew has requested a decision from the Board, as to whether it will recognize the two attendants as beneficiaries under the head of medical attendance.

"Dr. Bliss, in his statement, tells how the physicians were called into the case. Regarding himself, Dr. Bliss says that he was placed in charge, and was daily and nightly in attendance. The unremitting strain upon mind and body, accompanied by loss of sleep, produced the usual results, and besides losing thirty-eight pounds in weight, the doctor says that the sepsis of the patient was communicated to him, causing secondary abscesses, which lasted for upwards of three months.

"Dr. Bliss further sets forth that, in estimating the value of his services, the degree of responsibility should be considered, for, besides a skilful conduct of the case, he and his assistants were burdened with the hopes and fears of the nation. He had to give up his private practice, and when he resumed it again he was so prostrated as to be able to do but a small part of his usual labor. At the time the President was shot his professional income was $1,500 per month, and the first month he resumed practice after the President's death, his income was but $1,000. He estimates that his services to the President cost him $15,000, and insists that he should not only be reimbursed, but compensated, and that he is entitled to $25,000."

Tri-State Medical Society.—The eighth annual meeting of this society will be held at Terre Haute, Ind., September 26, 27, and 28, 1882.

Garfield Memorial Hospital.—On August 1st, according to the *Lancet*, a meeting was held in Queen Square, Bristol, to promote a movement for the erection of an International Hospital at Washington, in memory of the late President Garfield.

Compulsory Vaccination in Switzerland.—The French journals announce that compulsory vaccination has just been rejected in Switzerland by a *plébiscite*.

Prof. von Langenbeck held his last clinic on Saturday, the 29th of July. The amphitheatre was dressed with greens and flowers. The former assistants of Prof. Langenbeck in Kiel and Berlin have presented him with a handsome silver table service.

English Hospital in Jerusalem.—The Sultan of Turkey has given a site in Jerusalem, for the purpose of erecting a hospice and ophthalmic dispensary, under the auspices of the English branch of the Order of St. John.—*Louisville Med. News*, August 26, 1882.

Literary Notes.—Dr. Habershon's well-known work on *Diseases of the Abdomen* has been translated into Spanish by Dr. Jeinenez Verdigo, of Madrid.

Glasgow Medico-psychological Association.—At the annual meeting of the Medico-psychological Association of Glasgow, recently held, Prof. Gairdner was elected President, as successor to Dr. Hack Tuke.

The University of Berlin.—Prof. Du Bois-Reymond has been elected Rector of the Berlin University for the next two semesters, and Prof. Bardeleben Dean of the Medical Faculty.

Hip-joint Amputations.—During the past month, three cases of amputation at the right hip-joint were performed in England, with the aid of Mr. Davy's lever for controlling hemorrhage. A case where Mr. McLaren, of Carlisle, operated, lost two ounces of blood; a second patient, under Mr. Cowell's care, at the Westminster Hospital, lost three ounces; and the third case, where Mr. Paul Swain, of Plymouth, performed amputation with the assistance of Dr. Bampton, lost but one ounce and a half. All these patients are progressing favorably.—*Brit. Med. Journ.*, August 12, 1882.

The Common Mushroom.—Prof. Ponfick, of Breslau, has been making experiments on the common mushroom, and tells us in detail, and with the authority of science, what was somewhat vaguely known before, viz., that all common mushrooms are poisonous, but cooking deprives them in a greater or less degree of their poisonous qualities. The repeated washing with cold water, which they usually undergo to clean them, takes away a portion of the poison, and boiling does the rest; but the water in which they have been boiled is highly poisonous, and should always be carefully got rid of. Dried mushrooms are still dangerous for from twelve to twenty days; they require to be dried for at least a whole month, and are only really safe after four months' drying.—*Med. Times and Gaz.*, August 12, 1882.

Circulation of the British Medical Journal.—According to the report of the Council of the British Medical Association, at the meeting on August 8th, the weekly issue of the *Journal* now numbers 11,000 copies.

Monument to Schutzenberger.—The pupils and colleagues of the late Prof. Schutzenberger, of Strasburg, have erected a monument and bust to his memory. The bust was presented on July 6th, in an Address by Prof. Hergott, of Nancy.

"St. Jacob's Oil."—"St. Jacob's Oil" appears to be a feeble and badly made aconite liniment, and it consists mainly of water, ether, alcohol, turpentine, and a small proportion of aconite, with red coloring matter. Its whole function is to make money for the enterprising merchants who own it, and in this it is by no means a delusion or a snare.—*Squibb's Ephemeris of Materia Medica*, July, 1882.

A Curious Phenomenon.—The French journals, under this title, describe a flageolet player who charmed all his hearers by his musical performances at the recent fair held at Neuilly, an environ of Paris. He had formerly suffered from an attack of diphtheria. Tracheotomy was performed, and the silver tube which was introduced at the time of the operation, and kept stationary by means of a circular pad, now serves the musician of Neuilly as a natural aperture through which he breathes, and so successfully that his flageolet playing was enthusiastically applauded by all present.—*British Medical Journal*, July 22, 1882.

MATRIMONY IN JAPAN.—The Japanese Government has lately drafted new regulations for marriages. According to these, no man in the empire will henceforth be permitted to marry before arriving at the age of twenty. Women, however, are to be privileged to marry at eighteen.—*Med. Times and Gaz.*, July 29, 1882.

THREE HUNDREDTH ANNIVERSARY OF THE UNIVERSITY OF WÜRZBURG.—The University of Würzburg celebrated its three hundredth anniversary by a festival held from August 1st to 4th. Among the celebrities who received honorary degrees were Prof. Huxley and Sir James Paget. In his letter to the *Lancet*, Dr. Russell Reynolds, who represented the University of London, remarks on the stately decorum with which the whole of this proceeding was gone through. There was no applause either by voice or hand or foot; and there was profound, even solemn, attention directed to every word that was uttered. Even when Virchow and many other distinguished speakers left the rostrum there was no applause, but there was a slight vocal cheer when Canon Stubbs, of Oxford, finished his well-phrased speech, and when the representative from Amsterdam concluded his. Still further, it was very interesting to observe the entire absence of anything that elicited either a laugh or even a smile; there was throughout a pleasurable, not grim, sense of seriousness in the whole proceeding, such, as it seems to me, befits a great university act; and this was the more striking when contrasted with the overflowing hilarity at private entertainments, and in all the social gatherings of friends. At the festal dinner, Prince Theodor Carl (the cousin of the King), proposed the health of his Majesty. This was received with appropriate honors, the Prince alluding to his own personal relationship to the medical profession, he having passed through a course of medical instruction, and to the present time occasionally seeing patients in consultation.

Then followed a long pause between fish and soup, during which the talk of the guests and the tones of the band rendered it very difficult to do more than catch a few words from the nearest neighbors. Then, just as some of the visitors had swallowed a few mouthfuls of fish, silence was again called, the Rector rose, the waiters stopped, the guests stood up wiping their mouths, and the health of Kaiser Wilhelm was given and received with all honors, while the band played the familiar air of "God save the King."

Toast after toast followed, and pause after pause ensued, until seven o'clock was reached, when the guests departed, many to see their friends, many to the theatres.

In the evening there was a great gathering of the students and their friends, and of all who had come to the festival, in the great Ludwigshalle. If the official performances were singularly silent, this cannot be said of the "Banketfest der Studentschaft," the hilarious mirth of which was audible far beyond the limits of the hall. But good humor prevailed throughout, and the festivities were not prolonged until an unduly late hour.

Dr. Reynolds was sorrowful with regard to the painful spectacle of the gashed and disfigured cheeks, brows, and noses of dozens of students who were going about Würzburg and Heidelberg. Many had scars, of three to five inches long, on either cheek, some had slit noses, and were adorned with plaster as their only "decoration;" while some grown-up men were to be seen, who must have left their colleges for ten or fifteen years, still bearing these ghastly signs of early folly.

The man who has received his wounds in honest fight for his country or his home may be proud of what he has done, but he is not vain of his wounds. But these young men, of seventeen to twenty years of age, stamp about the street, or, curiously enough, ride in carriages behind a pair of horses, with their disfigured, and often injured heads, tossed high in the air, as if they thought it a fine thing to make day as well as "night hideous" in remembrance of something which has not been an honorable quarrel, but a form of strife for which few can entertain any feeling of respect.

DEATH OF DR. PIDOUX.—DR. PIDOUX died on the 4th inst., at his residence in Paris, from diabetic gangrene. He was more than an octogenarian, took his degree in 1835, and has been a member of the Academy of Medicine since 1864. Dr. Pidoux has written a great deal; but his principal work is his "*Traité de Thérapeutique et de Matière Médicale*," the first edition of which was published in 1839, in conjunction with the late Dr. Trousseau. He was for a long time principal physician at the Eaux-Bonnes, and was a great authority on matters connected with the therapeutic action of sulphurous waters. He was also Officer of the Legion of Honor.—*Lancet*, August 12, 1882.

DEATH OF DR. MCEWEN.—We regret to learn the death of DR. MCEWEN, of Chester, England, who became personally known to many American physicians during his visit to this country last summer.

DEATH OF PROF. HILDEBRANDT.—Our German exchanges announce the sudden death from apoplexy of PROF. HILDEBRANDT, the eminent teacher of gynecology in Königsberg.

HEALTH IN MICHIGAN.—Reports to the State Board of Health, for the week ending August 19, 1882, indicate that dysentery and typhoid fever have increased, and that bronchitis and influenza have decreased in area of prevalence.

Including reports by regular observers and by others, diphtheria was reported present during the week ending August 19, and since, at 14 places, scarlet fever at 9 places, measles at 4 places, and small-pox at 8 places, as follows: at Montrose, Genesee County, August 15; in Danbury Township, Ionia County, August 16; at Grand Rapids (1 new case), August 19; at Marquette (1 case, convalescent), August 20; at Portland (1 new case), August 21; in Walker Township, Kent County, and Orange and Sebewa, Ionia County, August 21.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT, U. S. ARMY, FROM AUGUST 22 TO AUGUST 28, 1882.

BILL, J. H., *Major and Surgeon.*—Granted leave of absence to Dec. 1, 1882.—*S. O. 196, A. G. O., August 24, 1882.*

ALDEN, CHAS. H., *Major and Surgeon.*—Granted leave of absence for three months.—*S. O. 196, c. s., A. G. O.*

MUNN, C. E., *Captain and Assistant Surgeon.*—The leave of absence granted him in S. O. 147, July 28, 1882, Department of the Missouri, is extended two months.—*S. O. 196, c. s., A. G. O.*

OWEN, JR., WM. O., *First Lieutenant and Assistant Surgeon.*—Assigned to temporary duty at Vancouver Barracks, Wyoming Territory.—*S. O. 114, Department of the Columbia, August 11, 1882.*

MACAULEY, C. N. B., *First Lieutenant and Assistant Surgeon.*—Assigned to temporary duty at Fort Columbus, New York.—*S. O. 147, Department of the East, August 25, 1882.*

ORIGINAL LECTURES.

ACUTE CATARRH OF THE MIDDLE EAR.

A Lecture.

BY OREN D. POMEROY, M.D.,

SURGEON TO THE MANHATTAN EYE AND EAR HOSPITAL, N. Y.

LECTURE II.

GENTLEMEN: At our last lecture we finished the consideration of the causes of acute catarrhal inflammation of the middle ear.

Prognosis.—As a rule patients make a good recovery. As has been previously hinted at, there is little tendency to destruction of tissue. If the membrana tympani ruptures, there is usually no loss of substance: only a fissure, which rapidly closes. I have seen such fissures heal in one or two days, although as many weeks may be occupied in repair. The favorable prognosis often turns on the short duration of the disease; for, if it is continued a certain time, changes of a proliferous nature are likely to occur. If the cavity has been completely filled with secretion and there has been great pressure, not relieved by rupture of the membrana tympani or evacuation from the Eustachian tube, the membranes of the round or oval windows may rupture, and labyrinthine complications result. The mastoid cells may be filled with the tympanal secretion, and take on true mastoid cell disease, or the inflammation may go direct to the cells by way of the antrum. Mastoid periostitis is not as likely to occur. The thing to be greatly feared in this disease is the obstinate catarrh of the pharynx, which so frequently accompanies the affection. Especially is this so in cases having struma or tuberculosis, where it sometimes seems impossible to overcome the difficulty. The same is true of many weakly, or at least sensitive, people, whose mucous membranes are constantly irritated by the harshness of the air, in many parts of this country, and the only means of relief seems to be a selection of an atmosphere congenial to the patient. I have seen a patient with pain in the ear, tinnitus, etc., changed to a more congenial atmosphere, when in a single day all the symptoms would disappear.

I infer that while a patient has a catarrh in the neighborhood of the Eustachian tubes, he is always liable to ear complications. One great danger is, that in the frequent relapses, which do not present very noticeable symptoms, the attention of the patient is not sufficiently drawn towards them, and treatment is neglected at a period when great deafness may result. I once had a catarrh patient go into the country for two weeks in midwinter, when he had a slight relapse of his symptoms, which were not treated until his return. The hearing had been fifteen inches for the watch, and it went down to three or four inches, from which I could never raise it.

In consequence of the proliferating changes in the Eustachian tube the latter is less under the control of the tubal muscles, and the patient may complain of crackling in the ears, due to the fact that the tube is frequently forced. Again, there is less of that opening and closing of the tube, which in a normal state maintains exactly the proper amount of air in the tympanum. If the tube be permanently narrowed, on the recurrence of a subsequent catarrh it is more readily closed than it would have been, had it been of normal calibre. This symptom may exhibit itself on very slight changes in the weather. In children, who have an ample Eustachian tube, it is less likely to occur, and may even be a source of safety where there are collections in the ear, which may have no other means of outlet, and which is often ample, thereby possibly preventing grave complications from the effects of confined matter in the tympanum. The altered and often sclerosed condition of the tympanal lining, I have often thought, acted as an exciting cause to future attacks, somewhat as the cicatricial changes in granular conjunctiva predispose to relapses.

The hearing ought to be perfectly restored. If the disease has continued long enough to thicken the tympanal lining, there will be some diminution in the sharpness of the hearing. A more important state is the collapsed membrana tympani. If the latter has remained in this condition for a few weeks only, it may never return to a normal position. It seems as though the membrana tympani, by its collapsed state, had become stretched, so as to increase the superficial area, when a sunken or cup-shaped condition was the more natural. I have seen patients with an abnormally patulous tube and sunken membrana tympani, who could restore the membrane by inflation, with improvement to the hearing, momentarily, but on the first act of swallowing were thrown back to the old condition, the membrane apparently remaining in proper position only when actually pushed outward by the intra-tympanal air-pressure.

From the fact that patients subject to catarrhal otitis often have an ancestry with the same tendency, it points at heredity. I am sure that the catarrhal and the rheumatic diatheses often seem to be a matter of heredity, and these affections are quite sufficient to cause ear trouble. Tinnitus aurium usually disappears, but it is not certain to do so, the catarrh setting in motion a tinnitus which may continue a part or the whole of the time during the remainder of the patient's life.

Treatment.—Although the *hyperæmia* is not as intense as in the suppurative variety, it is still quite decided, in some cases, and results in much pain and throbbing, and a sense of fulness in the ears. From one to three leeches may be applied to the orifice of the meatus, preferably to the posterior face of the tragus. The objection to applying them to the concha is, that they sometimes cause abscesses and erysipelas. There is no question, from my own experience, and from that of many others, that in this location depletion accomplishes much more than when applied elsewhere. After the leech has fallen off, encourage bleeding for one or two hours by bathing with warm water. In properly selected cases, the relief to pain and the feeling of fulness is most extraordinary. In other cases, the pain is aggravated by the leech, a dull, draggy pain being substituted for the former kind of pain. This being the case, I at once give large doses of morphia either hypodermically or otherwise.

It is worthy of remark that where the pain depends on a distended tympanum from inflammatory products, the leech will not relieve. In milder cases warm or hot applications to the ear are very serviceable. The most elegant method is to place warm or hot water into a rubber bag and lay it on the ear. The temperature should be regulated so as to give the patient the greatest relief. Very warm water will sometimes aggravate, so will too cool water. Latterly, it has been the prac-

tice of some to use cold or iced water. I can imagine it to do good in some cases of very excessive inflammation, of the sthenic variety, but I am, on the whole, timid about recommending cold to the ear. If it relieves the pain and throbbing and there is not directly afterwards a violent accession of inflammation, it is likely to be successful. We may be superstitious about the action of cold on the ear. Common salt heated and placed in a bag is a good application to the ear, or any dry agent susceptible of retaining heat is serviceable. A bottle of hot water wrapped in a napkin, with the ear laid against it, is an inexpensive and easily applied method.

Moist applications, from their macerating tendency, should be objected to, unless used for only a limited period. Even a hot flaxseed poultice may be applied for a brief period. The old-fashioned mode of applying the core of a roasted onion by its conical extremity to the meatus, may properly be recommended. A better plan for moist applications, is the direct use of warm water to the meatus; fill the latter with warm water, turn the head to the opposite side and let it remain for half an hour. A better plan still is to allow warm water to run into the ear from Clark's aural douche. This may be continued twenty or thirty minutes at a time, desisting when it relieves, or no longer feels pleasant to the patient. This method is very highly thought of by many surgeons of the best standing. I, on the whole, prefer the method of dry warmth. If the ear is excessively soaked with moist applications, it becomes at last very painful. Vapor of water gently blown into the ear often affords relief.

Sometimes chloroform vapor does well. Dr. Theobald, of Baltimore, instils a four grain solution of atropia into the meatus, even in children, to relieve pain. Any dilatation of the pupil will give warning if poisonous symptoms are likely to result. Magendie's solution of morphia may be used in the same manner. In young children a small pinch of black pepper wrapped in cotton will often relieve pain. It will be well for an adult to apply it to his own ear, and, if it burns excessively, diminish the amount of pepper or wrap it more deeply in the cotton,

Where there is a *collection* in the tympanum, the indication is to evacuate it. I do not always wait until the membrane bulges before I puncture. There are other signs of collection in the tympanum, besides this, which justify puncture and which have been already referred to. The operation is not specially painful; nay, it may be done without pain at all, in some instances. An instrument that the ophthalmic surgeon calls a broad needle with an extra long shank may be selected. Use a speculum which is large enough, on trial, for the needle to operate in, then with the forehead mirror carefully illuminate. Pass the instrument, held very lightly in the fingers, down close to the membrana tympani, for there is sometimes danger of pricking the canal. The puncture may be made at the protrusion, but if there is none, then select the posterior superior portion of the membrana tympani, for there will be the greatest depth to the tympanum. In children, owing to the excessive obliquity of the membrana tympani, the puncture may be directed upward, so as not to allow the point of the instrument to glance off from the membrane. While the instrument is in the act of puncturing, the tactile sensibility should be appealed to, and the surgeon should feel when his needle has punctured the membrane. In any event it is best to touch the inner wall of the tympanum—touch bottom, so to speak. Do not place the patient against a solid substance, lest he move his head towards the operator, and do himself harm. I do not usually use ether in this operation, but with many the anæsthetic is the favorite method. I never operate as well with the patient in a prone position: one seems to be out of his reckoning—the relations are not natural. I believe a quick, delicate, and gentle thrust is the best method.

If the operation takes on the form of a somewhat lengthy incision, then a knife like Gruber's, with a handle affixed at an angle, is the best plan, for every step of the operation may then carefully be observed. It is proper to state, however, that an instrument of this kind is much more difficult to operate with than the straight one. If after the puncture, no fluid is evacuated, then perform Politzer's inflation, and the sero-mucus may be seen to flow out. If the head is turned towards the affected ear, then the whole of the tympanum may be emptied. The inflation should be repeated until the perforation whistle is elicited. The paracentesis may be repeated as often as the tympanum refills, or by a strong inflation the puncture may be reopened, or, if this does not succeed, pass in a No. 1 Bowman probe. This operation, not only relieves pain in a most wonderful manner, but has an equally astonishing effect on the hearing. I remember a case where I suspected an accumulation in the tympanum, with a collapsed membrana tympani, and I punctured and evacuated not more than two drops of serum, with a very great improvement to the hearing.

The profession are indebted to Prof. Schwartze, of Halle, for this operation of paracentesis, which has contributed so much to our surgical resources.

Another condition of great importance and requiring attention is the *collapsed membrana tympani*, consequent on the closure of the Eustachian tube. It has already been seen that this is sufficient to cause considerable pain to the patient and often needs prompt attention. At the outset, I am inclined not to inflate if there is considerable hyperæmia, as it sometimes adds greatly to the patient's suffering; but after a day or two it certainly would be proper to make the attempt, but let it be done gently. At first it may occasion sharp pain, but usually it gives great relief. Do it by Politzer's method rather than by the catheter, as the latter may irritate or lacerate the inflamed throat and do mischief. The rule, then, is inflate very gently at first, and if it acts well continue it, and if there is too much pain, desist. The inflation should be done sufficiently to elevate the hearing to the highest attainable point. If this point is passed, and the hearing diminished, and tinnitus and pain result, then direct the patient to hold his nose and swallow several times; this will empty the tympanum of excess of air, and again restore the hearing, provided the tube is not too swollen to open upon muscular contraction. The latter not being the case, air will be confined in the tympanum, and may for a while aggravate the symptoms.

This is one of the objectionable features of inflation. It is a good rule to do nothing to the patient which may occasion any throbbing or pain in the ear. Manipulations which are not altogether gentle, or even the mildest syringing may do harm by adding to the existing hyperæmia. Even the leeching must be done by a careful hand, for rough manipulations have before now caused a return of the pain, which the leech had relieved.

The inflation for the restoration of the collapsed drum-head is only a temporary measure, and the *tubal catarrh*, which is the cause of the trouble, should be treated. Sometimes a case may be so mild, and show no symptoms of disease except in the Eustachian tube, that the diagnosis of tubal catarrh may very properly be made. This condition may be met in the following manner: simple salt and water warmed, and of the strength of a drachm to the pint, may in mild cases suffice. Throw it behind the velum by means of a spray-producer or the posterior nasal syringe. I prefer the one devised by myself, which has a tip separated from the

syringe by a rubber tube. I use my own hard-rubber spray instrument; any other may be used; the glass instruments are the best, but they often break. Do not throw up more than half an ounce or an ounce of the salt and water, and do it very gently, instructing the patient to remove it at once by expectoration. The atropia-dropper may be used for this purpose, the fluid being thrown into the anterior nares; but in all these applications do not allow the patient to be frightened or agitated, for he may cough, sneeze, or swallow, so as to allow the fluid to enter the tympanum.

Some years since, in Vienna, I saw Dr. Adam Politzer using for this purpose a little earthenware vessel having a nozzle which fitted the nostril, similar to our sick-feeder, which he used by pouring the fluid into the throat. When this medication is insufficient, chlorate of potash in saturated solution may be used, or carbolic acid, one drachm to the pint of water. It may be necessary to give the patient general treatment for naso-pharyngeal catarrh.

Where more energetic measures are needed, I employ the nitrate of silver. It may be used with the posterior nasal syringe or spray instrument, the Eustachian catheter, or my own faucial catheter. The strength may be from a few grains to the ounce, to a one-hundred grain solution. When a drop or two is used by either of the catheters, or with the spray instrument, a much stronger solution will be borne. In using the posterior nasal syringe it is a good plan to draw up five or ten drops of a ten or twenty-grain solution, and force it in strongly enough to cause a coarse spray to be produced. If much pain results, throw in two or three drachms of salt water, which frequently, but not always, gives surprising relief. If the solution has been too strong, the tube may swell, and for two or three days become somewhat impervious. If a prolonged soreness is left in the throat, the remedy has been too strong. There ought to be a feeling of relief from the application after a few minutes or an hour or two. Tincture of iodine may sometimes be used, but only one to three or four drops should be thrown up at a time. It may be diluted with alcohol if necessary; it is sometimes painful. Chloride of zinc acts somewhat like nitrate of silver, but it is occasionally a harsh remedy. Many other astringents may be used, being careful to reject any that act badly. It is not possible to determine beforehand which remedy will be the most beneficial. Often sore and painful tracts of redness, with pain on deglutition, may be observed. The best plan is to touch these with a twenty to forty-grain solution of nitrate of silver, using cotton on a holder for the purpose. Although it is a harsh remedy, I know of nothing which will so soon abolish the pain and inflammation.

Often at the outset of an acute catarrh with pain in one side of the throat which shows a tendency to travel up the Eustachian tube to the ear, the whole process may be arrested at once. A patient was treated by mild remedies without effect. On returning home after one of these applications, the pain was aggravated; it could be followed up the Eustachian tube to the tympanum; the latter began to throb painfully, and in desperation I poured a freshly made forty-grain solution of nitrate of silver into a hard-rubber spray instrument, and threw up a decided spray for two or three seconds behind the velum, pointing it towards the Eustachian tube. It caused considerable pain for fifteen or twenty minutes, but the symptoms wholly disappeared, and no further treatment was necessary. A somewhat threatening attack was evidently wholly aborted.

I am aware that nitrate of silver often acts injuriously, exciting severe pain, and causing much soreness of the parts, which may remain for days or weeks afterwards. The question is to select the cases in which it is likely to act favorably. The above indication of *pain and localized soreness* I believe to be favorable to the remedial action of nitrate of silver. I have in some instances, applied a strong solution of the arg. nit. to a painful and hot locality in the upper part of the pharynx, the result of inflammation, where it produced no pain whatever, but actually felt cool and afforded the most grateful relief. The principal trouble seems to be that the patient does not in some cases appear to react successfully from the application. Sometimes steam injected against the mouth of the tube, and often into the tympanum, acts well in reducing the engorgement of the Eustachian tube. The hard-rubber catheter should be used for this purpose, as the metallic instrument becomes too much heated; it requires to be fixed in position by the catheter holder; I believe my own instrument is a sufficiently good one for the purpose. Do not prolong the sitting beyond four or five minutes, giving a few puffs, and then waiting a half minute, and then repeat. The first effect will be to congest the lining of the tube, but subsequently the hyperæmia will be diminished. I would not make applications to the throat oftener than once in two days, unless it be some remedy of the milder variety, like carbolic acid, a drachm to the pint; this may be used, perhaps a little diluted, in the upper pharynx with a Davidson spray instrument by the patient himself, two or three times a day, but avoid any unpleasant irritation of the part.

Prophylaxis.—Inasmuch as this disease depends largely upon the habits of the patient, and climatic influences, much may be done to prevent recurring attacks. Everything that tends to excite a "cold" should be scrupulously avoided. It takes years of experience to live wisely in this respect; it is only those who become somewhat venerable in years, who may be seen carrying an umbrella almost habitually, with an overcoat on the arm or actually wearing it, and with properly shod feet, who regulate the temperature of the body as carefully as a chemist does a mixture which must be kept at a given temperature to ensure the success of an experiment. Patients subject to aural catarrh become surprisingly sensitive to any lowering of the temperature. I have known patients to observe the direction of a draft, by a pain, or an unpleasant feeling in the ear, when no other signs of its presence existed. They seem to be as sensitive to atmospheric changes as an habitually rheumatic patient, and it is scarcely possible to make the statement stronger. Riding in the wind is often extremely pernicious, and the patient should have the ears protected by cotton-wool in the meati or some other mode of protection. Wet or damp feet or damp clothing must be avoided, or on returning from a ride or walk, everything damp should be removed and dry clothes substituted. The action of peculiar atmospheres has already been hinted at.

I believe *nothing* exerts so strong an influence on the well-being of a catarrhal patient as congenial air. It would seem almost as important as in the case of an asthmatic patient. If one remains in an atmosphere which constantly congests the lining of his pharynx and Eustachian tubes, it is well-nigh impossible for him to do well, but he is likely to go on adding to his deafness by successive attacks, until great hardness of hearing may result. Another important indication is to cultivate as vigorous a state of the general health as is possible, thus enabling the patient to resist the ill effects of our climate.

I do not believe in avoiding the out-door air to prevent taking cold. I have noticed that our stage-drivers rarely suffer from catarrhal affections, notwithstanding they are on their boxes driving sixteen or eighteen hours a day, and exposed to all weathers. Their vigorous physiques resist the catarrhal influences, and this

state has been brought about by constantly being in the open air. Careful regulation of all the habits, is a more important matter than is usually supposed.

Tuberculous or strumous patients may require, in addition to a nourishing diet, stimulants and cod-liver oil, the latter in some form of emulsion. Excessive fatigue or exhaustion should be avoided, as diminishing the power of the constitution to resist the effects of cold. I know a gentleman who will never admit that he has overworked or become exhausted, but he suffers frequently from "a cold" which seems always to attack him in times of depression. Even in mid-summer the inclement atmosphere follows us. I have observed those who go into the country suffer especially. The mid-days are excessively warm, but the evenings often are cold, the temperature after sundown going down very suddenly, and blankets may be in requisition.

It is advisable to direct the patient to always breathe through the nostrils when possible. One of the best plans for keeping the nostrils free is to constantly breathe through them, besides the favorable influence of a current of air passing across the faucial orifices of the Eustachian tubes. This matter will be developed more fully under the head of naso-pharyngeal catarrh, etc. If the mouth only is used in breathing, air is insufficiently warmed, and it irritates the pharynx. Sometimes I advise a respirator to be worn over the mouth, so that the air may be rendered less irritating to the throat. From what has been said, I hope you are impressed with the idea that it is almost a fine art to protect the system properly from our variable and inclement atmosphere.

Constitutional treatment has already been hinted at in the previous topic. To those who accuse us of treating disease locally and depending on it, I would say that I am most heartily in favor of doing anything that benefits the patient. Some of our therapeutic friends will tell us that a large dose of quinia acts favorably in a commencing sore throat, may break it up in short. Tr. aconit. rad. is also given for the same purpose. Others take pleasure in breaking up threatening symptoms by a large dose of Spts. vin. gal., or something of the kind. In the outset of an attack it may be broken up by somewhat prolonged and excessive perspiration in bed, with or without a cathartic dose. A warm foot-bath is a very harmless and effective mode of inducing perspiration, or bottles of hot water may be placed at the feet and sides of the patient to accomplish the same purpose. If there be no undue obstruction in the bowels, a large dose of morphia may suddenly avert the disease. A full dose of Tr. of guaiac may sometimes be very serviceable.

SOME OPEN QUESTIONS IN MEDICINE,

WITH A RUNNING COMMENTARY ON THE NATURE AND TREATMENT OF DIPHTHERIA.

BY RICHARD McSHERRY, M.D.,

PROFESSOR OF PRINCIPLES AND PRACTICE OF MEDICINE IN THE UNIVERSITY OF MARYLAND.

Is it not strange that nearly every apparently simple question in medicine may become a *crux* to the medical investigator, so that unless he has that docility of mind which will accept the *ipse dixit* of a master, whom he follows and is willing to swear by (*in verba magistri jurare*), he is fain to content himself with the aphorism that "there is a great deal to be said on both sides of the question?" What is diphtheria? Is diphtheria croup, and is croup diphtheria? Call the ayes and nays, and the vote seems to be about equal, and it rests with the caller himself to give for his own satisfaction the casting vote.

Is the malignant disease which we commonly call cancer, a constitutional disease with local developments, or a local disease primarily, affecting the whole system secondarily? Again, the votes by the sound are about equal.

Is bloodletting a proper remedy in acute inflammation? Aye and nay come down upon us from remote ages. In the face of an appalling opposition I believe bloodletting to be the most potent, if not the safest, of antiphlogistics. Like all potent remedies, making prompt and decided impression, it is, when in fashion, liable to great abuse. Dr. Sangrado is a good caricature of the abuse of the agent when "blood-him," was the fashion, but, nevertheless, *abusus non tollit usum*, and bloodletting is a remedy now too much neglected. I could give "modern instances" from my own practice of its usefulness if there is any rational means of judging of cause and effect in medicine. I was pleased to find some time ago in conversation with my distinguished friend, Prof. S. D. Gross, that he has ever held to the same views and practice.

While touching upon this subject, I may mention an interesting reminiscence in regard to bloodletting in pneumonia. I have always taught in my lectures that some cases, in conditions at the time expressed, *demand* bloodletting, local or general.

During the late unhappy war, the views of Todd and Hughes Bennett were exerting a mighty influence, and bloodletting was quite discredited, except that effected by the sword and other implements of war.

I abhorred this method, while measurably respecting the surgical. It happened that among our pupils were two very intelligent medical cadets then serving in army general hospitals near the city. When examining these young men for degrees, I took occasion to examine on pneumonia, and questioned both in regard to what they had read and what they had seen. We will call them Mr. M. and Mr. K. They were both attached to very large hospitals, and had seen great varieties of injuries and diseases. Mr. M. had seen a great many cases of pneumonia. What was the treatment? *Ans.* Generally stimulating.—What was the result? *Ans.* The mortality was large.—How large, fifty *per cent.*, more or less, of the patients? *Ans.* Much more.—My expression must have been one of surprise, for the candidate immediately added: "Professor, a great many of the cases come into the hospital far advanced in the disease, and some actually moribund." I then said that stimulation was probably the best your surgeons could do for them, but had any of these men any marks about them to show general or local abstraction of blood? *Ans.* They had not.

When Mr. K. came up, I took him over the same ground. He had seen a great many cases of pneumonia in hospital about one half of which proved fatal. The treatment was stimulating, *à la* Todd. Were any bled before or after coming under your observation? *Ans.* They were not: I never saw a man bled in my life.

Mr. K. (now Dr. J. H. Kidder, U. S. N.) after passing a brilliant examination before the navy board, called to pay me a friendly visit. I referred to his hospital experience, and asked how the surgeons explained the large mortality in pneumonia? His answer was that they supposed the lost cases had not been sufficiently stimulated. And I remember, said I, my young friend, when it would have been said the men died because not sufficiently depleted in the early stages.

I mentioned these same facts some time after their occurrence to a practitioner in this city who had been employed as a civil surgeon in one of the hospitals in question. The gentleman said that he remembered distinctly two cases of recovery, both of which had been freely cupped!

Are not such facts worthy of note, *per contra*, as offsets to the statements of Bennett and Todd, that when pneumonia proved fatal, it was rather due to the treatment (by bloodletting) than to the disease?

Drs. Bennett and Todd were both very able men, as able as any in our profession, but they were as liable to mistakes as the rest of us. *Requiescat in pace.*

To come back to diphtheria, with its vexed questions, its identity with croup as Morell Mackenzie *et al.* contend, and as Niemeyer *et al.* deny. Thus Mackenzie says:

"The ordinary inflammation of mucous membranes is attended with engorgement of the tissues and the formation of pus on the surface; under the influence, however, of a certain poisonous contagium, the inflammation, instead of being attended with the formation of pus, leads to the exudation of layers of lymph which become adherent to the free surface of the mucous membrane. This disease is called diphtheria, and whether the lymph is deposited on the mucous membrane of the pharynx, or larynx, or trachea, or bronchial tubes, or any other mucous membrane, or on a wounded surface, the disease is still 'diphtheria.' To suppose that there are two kinds of pellicular inflammation of the larynx, one of which is the cause of the diphtheritic poison, and the other in which the cause is some other undiscovered influence, is totally opposed to all probabilities."—*Diphtheria, its Nature and Treatment*, by Morell Mackenzie, M.D.

Among the points of distinction usually made by those who deny the identity of croup and diphtheria, two very prominent ones are thus met by this author:

1. Albuminuria is assumed to be distinctive of diphtheria. But, says Mackenzie, albuminuria is often present in croup.

2. The cervical glands are affected in diphtheria, but not, or rarely, in croup. The reply to this is: "the cervical glands are not often affected in croup, because the mucous membrane of the larynx has no communication with the superficial cervical glands; on the other hand, as stated above, there is an elaborate connection between the pharynx and the lymphatic glands."

Developments of disease often deviate from the course laid down for them in the text-books. I have just ceased attendance upon a most alarming case of diphtheria, or diphtheritic croup, in consultation with Drs. Jenkins and O'Donovan, in which there was abundant development of diphtheritic membrane upon tonsils, pharynx, and posterior part of uvula, giving a border to the anterior edges, in which we could detect no enlargement of any of the cervical glands. I will recur to this case when speaking of treatment.

Niemeyer expresses himself thus:

"The diphtheritic pseudo-membranes, or sloughs, result from superficial gangrene of the mucous membrane, which again depends on compression of its nutrient vessels by an interstitial fibrinous exudation, or from swelling of the tissue elements, which are filled with a cloudy substance. If the larynx and trachea participate in the disease, the croupous, not the diphtheritic, form of inflammation of the mucous membrane occurs; that is, the surface of the mucous membrane is covered with a more or less tough and consistent false membrane, which may readily be removed, and leaves no loss of substance after its removal. This circumstance has induced some physicians to identify primary genuine croup, which is due to catching cold, etc., with croupous laryngitis caused by infection with diphtheritic contagion. I consider this a false view. The division of diseases, according to the pathologico-anatomical changes they induce, is only a make-shift. In all cases where, as in genuine and diphtheritic croup, we find that the anatomically similar diseases of nutrition depend on very different causes, we should consider them as distinct."—Niemeyer's *Practical Medicine.*

I have quoted these two authors as good observers, and as representative men of opposite opinions, who respectively agree and disagree with all the eminent writers on the same subject.

Are such discussions merely about words? Is it not certain that some cases would be considered typical of diphtheria, and others typical of croup? If this last word has any definite meaning, no one would apply it to a deposit about the fauces, with fever and prostration, provided there were no invasion of the larynx, no marked change of sound in voice, cough or respiration. And perhaps no one would call an attack by any other name than croup, if the initial symptoms were strictly laryngeal or tracheal.

How far may contagion or infection be taken as causative agency to distinguish between diphtheria and croup? Is there any difference in this respect? Croup has not usually been considered infectious or contagious; diphtheria is considered to be notably so. "An acute specific disease, both epidemic and contagious, characterized by a special inflammation of the mucous membrane," etc., says Dr. Squire, in his definition of the disease, while he makes no reference to contagion or infection when speaking of croup.—Reynolds' *System of Medicine.*

This ought to settle the question, but we all see cases of diphtheria where little or no care is taken to prevent its spread, without any extension whatever. I have attended a great many cases where mothers and nurses seemed utterly indifferent to risks, notwithstanding these being plainly presented to them; yet I have seen very few instances of obvious contagion. I certainly admit risks, contagion, and infection. In one family of three children, all affected one after another, there had been free kissing and caressing before I was called in. Professor Frick, of the University of Maryland, early distin-

guished, and of brilliant promise, fell a victim to a tracheotomy operation and the use of a blow-pipe passing from his mouth to the trachea of a diphtheritic child in the hospital.

Notwithstanding such positive facts, the negative facts stand out that, in a vast number of instances, an isolated case occurs in a family without any extension whatever, and where little pains are taken, if any, to prevent extension. Withal, however, the physician is very culpable who does not insist upon precautions. They may save life; they can do no harm.

Supposing diphtheria to be assuredly contagious, what is the contagious matter? Is it living or dead, animal or vegetable? Here is another field for discussion, and discussion develops the reasoning faculties of the profession, always becomingly active, for do we not know

> "That none but a clever dialectitian
> Can hope to become a great physician.
> That has been settled long ago."

The contagion is probably carried in the vitiated secretions, and more probably in living germs lodging therein. Does the morbid poison affect the mucous membrane, let us say of the fauces, and thence the blood, or does it enter the blood first, and then make its impression on the mucous membrane secondarily? Are the low organisms found, always, perhaps, upon careful examination, in the false membrane, in the blood, and the various tissues and organs, to be reckoned as cause or result? Are not the same low organisms, always or usually floating about us, like the moats in the sunbeam, and do they produce the obvious diseases, or do they flourish because diseased blood or tissue is only unable to resist them? A poor old drunken pauper was found helpless in a field the other day, who was attacked by turkey-buzzards, and they would have devoured him, because he was not capable of resistance, had not some neighboring good Samaritans rescued him from their clutches. The buzzards did not cause him to be old and cadaverous, but finding him so, they would have picked the flesh from his bones in short order, according to their instinct, if they had not been driven away.

It is certain, or seems to be certain (a poet, by the license of his craft, goes so far as to say,

"The first and last word in life's volume is doubt"),

that low organisms are deeply and essentially involved in the pathology of diphtheria. Positive evidence comes from a great many sources, and outweighs negative evidence.

While writing this paper a very interesting article falls under my notice in the columns of THE MEDICAL NEWS, from the pen of Dr. John M. Keating, entitled "The Presence of Micrococcus in the Blood of Malignant Measles; its Importance in Treatment."

After all, treatment, therapeutics, is the paramount business of the American physician, and perhaps not only in malignant measles, but in a great many other malignant diseases, the most important element in successful treatment is the destruction of those ravenous parasites known by the various names of micrococci, bacteria, etc. I have long been of this opinion, and have acted upon it with considerable success.

Dr. Keating (and Dr. Formad) found in malignant measles that micrococci (sphero-bacteria) were, as it were, devouring the blood, especially the white corpuscles, of the patients. For a time there was very considerable mortality among the children, and the presence of the bacteria led to the question as to Dr. Formad's experience of the means of checking the development of micrococci in his culture solutions. He said that alcohol was the most potent agent. I may refer the reader, for the beneficial change effected, to the original article, where the patients were liberally dosed with whisky.

Let me reproduce some brief passages from Dr. Keating's paper:

> "We may look at present upon the micrococcus as associated with the malignant symptoms of all complications known as 'blood poisoning.' It is found in erysipelas, in puerperal septicæmia, in diphtheria, and in malignant measles. Experience has also taught us that alcohol, the vegetable acids, calomel, or corrosive sublimate, are the drugs *per se* in septicæmia.
>
> "The action of alcohol and calomel is too well authenticated in puerperal septicæmia to doubt their efficacy.
>
> "We know of late how surprising a result will often attend the use of alcohol and *corrosive sublimate* in malignant diphtheria, and also the value of vegetable acids, especially lemon juice and claret, in this dreaded disease."—MEDICAL NEWS, July, 1882.

This all goes to show that if we protect the blood from the ravages of the micrococci, we render something of the same kind of service that the neighbors did to the old man when they rescued him from the buzzards.

Dr. Keating says we know "of late of the value of corrosive sublimate in the cure of diphtheria." I have used this agent habitually for many years, and can add my testimony to the facts recently adduced.

My friend and colleague, Prof. Chew, of the University of Maryland, after speaking of this subject, was kind enough to send me recently a copy of Prof. Pepper's "Address on Medicine," wherein he relates a case, now famous, where, acting upon information given by Dr. G. A. Linn, Dr. Yarrow and himself carried a child safely through a desperate condition of diphtheritic croup, principally by the therapeutic agency of corrosive sublimate. I read this with great interest and satisfaction. It was to me confirmation of my own teaching and practice for years.

It is strange how such an important agent should have dropped out of sight. In the Index of Therapeutics, Stillé and Maisch (1879), no mention is made of mercury under the head of diphtheria; and none in Bartholow's Materia Medica (1878).

In the work of Meigs and Pepper, on Diseases of Children (1870), we find the following passage:

> "Regarding diphtheria as a constitutional affection, depending upon a peculiar alteration of the blood, we must admit that we are in possession of no remedy which in any respect merits the name of a specific in its treatment.
>
> "Among the best internal remedies, however, are the

various preparations of chlorine, iron and bark, which may be given singly, or, preferably, in combination."

Here is no mention of mercury, but in the chapter on the allied (identical?) disease called *croup*, mercury does not pass without mention.

"Since the publication of the last edition of this work, our increased dislike of the administration of mercury to children, in large and frequently-repeated doses, and the constant observations that even its free use does not appear to arrest the course of true croup, have led us to abandon entirely its employment in this disease."

True croup is so intractable to treatment that one scarcely knows in what remedies to trust; but I may observe here, *en passant*, that several of the best practitioners known to me trust more to calomel than to any other one remedial agent.

Perhaps Dr. Pepper may be led to reconsider his expressed opinion, since he finds mercury so important in the cure of diphtheria.

By the way, it may not be amiss to offer here an illustration showing the force of some of Dr. Pepper's arguments in relation to mucous catarrhs of a local character, without any connection with blood poisoning.

Dr. Lamousin reports a case "*Du croup par cause externe*," wherein a healthy child of four years of age had a violent attack of diphtheritic croup from swallowing, *de travers*, a kidney-bean. The disease was so typical that the doctor discredited the story of the bean as told by the parents. But the foreign body really entered the larynx and developed the croup.

"Il ne s'agit pas, en effet, d'accident, simulant plus on moins la laryngite diphtheritique, mais bien de cette maladie elle-même, avec son cortége de symptomes, notamment le plus caracteristique de tous: l'expulsion d'une fausse membrane tubuleuse."

False membrane was thrown off pretty freely for several days, under the use of antimony, in masses and fragments. Some of the membrane was, "très-résistante, tubuleuse dans une partie de son étendue; sur sa face externe se voient de petits tractus rouge vif comme des rudiments de vaisseaux sanguins."

The case was, indeed, altogether characteristic; in a few days, something was heard like a valve or piston working up and down in a pump, and thereafter a half bean was ejected enveloped in bloody mucus. The cure was then immediate. There was at the time no prevalence, indeed, no case, of diphtheria anywhere in the community.—*Annuaire de Médecine, etc.*, 1865.

As to the treatment of diphtheria, I must say, that upon theoretic grounds, confirmed by practical experience, I give the *first place*, ordinarily, to the use of corrosive sublimate. It would, perhaps, not be easy to say why I adopted its use years ago, except from noticing its magical influence over specific sore throats. (How perpetual and enduring the alliance between Hermes and Aphrodite!) Then if it relieves one poison affecting the throat so readily, why not another? At all events, I have used it advantageously and satisfactorily for years.

I believed with Dr. Jodin, of Paris, in the presence and influence of a parasite, a *contagium vivum*, accepting to a certain extent his dicta: 1. That the concretions, the source of all the symptoms, are products of parasitic or vegetable origin; and, 2. That the basis of treatment consists in the application of topical parasiticides, a medication as rational as it is happy in practice.

But this view is not quite broad enough, so I agreed yet more fully with Dr. Laycock, who believed the parasite to be in the blood, as well as in the false membranes, and who says summarily, "that antiseptics and parasiticides appear to be the most efficient remedies in diphtheria. I can speak most favorably of the sesquichloride of iron and hydrochlorate of potassium."

These two agents, indeed, seem to be in universal use, but in addition, I very often make the iron the vehicle for the corrosive sublimate. I give, for example:

℞.—Bichlor. Hydrarg. . . . gr. j.
Tinct. Ferri. Chlor. . . ℥ss–℥j.
Potass. Chlor. . . . . ℥ij.
Aq. . . . . ℥iij—M.
S.—Teaspoonful as directed, in sweetened water.

I find among my prescriptions such a formula as follows:

℞.—Hydrarg. Chlor. Corros. . . gr. j.
Ammon. Chlor.
Potass. Chlor. . . . āā ℥ij.
Aquæ, ... Oj—M.
S.—To be used as spray and gargle, as directed.

The spray is often pressed too hurriedly by the attendants to the annoyance of the patient, to whom it may become very repugnant; a puff of spray and a free inspiration of air, alternated, will usually be well borne.

In a case under the care of Dr. Jenkins recently, to which Dr. O'Donovan and myself were called in consultation, we gave the exact doses as directed by Dr. Pepper (or Dr. Linn), with the happiest effect. When I first saw the child the visible exudation had nearly disappeared from her throat, but the larynx was deeply affected, and the bronchial tubes, with pretty rapid extension to the smallest ramifications; in other words, there was capillary bronchitis. Dr. Jenkins had used iron and chlorate of potassium freely, and had commenced the use of the mercury before my visit. I concurred fully in the measure, recommending the mercurial spray also. Without going into the details of a grave case of diphtheria, I may say that for some days the child appeared to be so near death that any change for the worse must have been fatal. It was a question whether she would go by asphyxia or asthenia. Meantime the mercury was given every two hours, terebinthinate and ammoniated liniment frictions were made to the chest repeatedly, and oelate of mercury (ten per cent.) was rubbed upon the throat. Twice emetics were given of ipecacuanha and alum, which brought up some loose membrane and gave some relief to the distressed respiration. Beef tea and milk toddy were given as nourishment. She was not neglected for one moment by her family and nurses during the critical time, and at length we saw her convalescence fairly established.

This was one of three very ill cases I have recently attended and treated with corrosive sublimate, all

now well, or well advanced in convalescence; for one young lady, after being free from all the primary symptoms, had obscurities of vision, paresis of the limbs, formication, difficulty in swallowing, and so much tumidity about the jaws and face, after I had ceased regular attendance, and made but occasional calls, that I apprehended a secondary nephritis. One or two specimens of urine, taken at intervals of several days, gave about the same results: Sp. gr. 1036, acid reaction; no albumen to heat and nitric acid, but some fermentation when the acid was added. White earthy deposit with Moore's test, and crystals of nitrate of urea when exposed with nitric acid.

It is about three months since the beginning of her attack, anæmia and partial paresis are still among the sequelæ, but her health steadily and slowly improves.

I mention these cases, if not very remarkable in themselves, still as confirmatory of the value of the mercurial treatment.

Dr. Pepper's recorded case must exert a widespread influence.

Perhaps all physicians habitually use alcohol in some form in serious cases of diphtheria, but, taking a point from Dr. Formad's expressed experience, I shall use it hereafter not for the single agency of support, but also for its germicide properties. It may be remarked, by the way, that nearly all the remedies highly commended by practical physicians have in a greater or less degree these same properties, upon whatever theory they may be administered.

In conclusion, let me ask how often diphtheria may recur in the same subject? I have seen secondary recurrences, but scarcely two fully developed attacks in any one individual. Some months ago I was attending a boy with an attack of it, when a little girl, a neighbor, stopped me as I left the house to inquire for her playmate, and she took occasion to inform me that she had suffered with attacks of diphtheria seventeen times. I asked what physician had carried her so safely through, when she informed me that it was Dr. ——, of the infinitesimal school. I did not wait to get any details of diagnosis, pathology or treatment, and therefore can give no further information than in regard to the surprising number of attacks and recoveries.

BALTIMORE, August 2, 1882.

A CASE OF LONG-STANDING NEGLECTED UMBILICAL HERNIA,

RESULTING IN PERFORATION OF THE ABDOMINAL WALLS AND DEATH.

BY W. B. BARHAM, M.D.,
OF NEWSOM'S, VIRGINIA.

THE following case will, I think, be of interest to the medical profession. It terminated fatally in a few hours, and its only interest hinges upon its rarity.

On the 1st of August, 1881, I received a note from Dr. E. C. Barrett, asking me to see, with him, Mrs. E. J., aged 43, the mother of several children, and weighing about 250 pounds. He described her as being in a very curious and critical condition, and upon reaching her residence I found her suffering extreme agony, and almost in *articulo mortis*. After an examination of the case, we consulted with her husband and friends, in order to arrive at its correct history, and found that for the past four years she had, to use their language, been carrying an "immense bag," reaching from her abdomen to the knees, and that on the morning of the day on which we were called to see her, as she was ascending a flight of steps, perforation of this bag had taken place, and that her intestines had protruded. When I saw her they had protruded to the extent of about twenty feet, and were lying by her side on the bed, in a mass that would fill a half-bushel measure. After a careful examination, we found the perforation near the umbilicus, which, by the weight of the tumor, had been dragged far below its usual situation. The perforation was not more than three inches in circumference, and it was constricting the mass so tightly that it was in an almost gangrenous condition. After a hurried consultation, we concluded that the only shadow of hope for the patient was to enlarge the opening and to replace the intestines; but so great was her exhaustion, that we were fearful that she would die before the operation could be completed. The rupture occurred early in the morning, and it was two o'clock P. M. before either of us saw the patient, and it was four o'clock before we could begin the operation. After I had given her about a gill of whiskey, and had anæsthetized her, Dr. Barrett enlarged the opening to the extent of about four inches, and then came the "tug of war;" for, notwithstanding our most strenuous efforts, it took us at least an hour and a half to replace the intestines, and this having been at last accomplished, we brought the edges of the wound together, as best we could, with silk thread. After the operation was completed we again administered a gill of whiskey, after which the patient partially revived from the effects of the operation, but died from exhaustion in about two hours.

Remarks.—This case is reported because I believe it to be uncommon. I have consulted all the surgical authorities accessible to me, and find that there are few such cases mentioned. Dr. Agnew, in his "Principles and Practice of Surgery," vol. 1. page 497, mentions the case of an Irish woman, once under his care, in which ulceration and sloughing of the abdominal tissues took place. I am well aware that umbilical hernia, especially in obese women and those who have borne many children (and this was the case with our patient), often occurs; but such a termination of umbilical hernia as here reported I claim to be rare, and for that reason I thought that this case might be of interest to the profession.

Of course, nothing is claimed as to our treatment. We did all we could, but it was one of those cases which, unfortunately, too often occur, in which our best efforts mock us. We had but little hope for the patient from the first, but a desire to do something for her, and to give her the benefit of the chance of recovery, slight though it was, prompted

us to perform the operation. The perforation of the abdominal walls took place early in the morning, and it was several hours before either of us could see her. In the mean time exhaustion and gangrene of the intestines had done their fatal work; whereas, could we have seen her at once, the case might have resulted more favorably.

Her husband informed us that the hernia appeared about four years ago, as a lump about the size of his fist, at the umbilicus, and that it gradually increased in size, until the rupture of the abdominal walls took place. In this case it is probable that the parts covering the hernia became attenuated, the peritoneum and fascia disappeared by absorption, and the contents of the tumor came almost directly in contact with the skin, and this condition continued until, upon the exertion of ascending a flight of steps, the abdominal walls ruptured, and protrusion of the intestines took place.

No doubt such a termination might have been prevented, had the patient submitted to surgical treatment when the tumor first appeared, but notwithstanding the urgent appeals of her husband and friends, she persisted in her refusal to submit to such treatment, until neglect resulted in death.

MEDICAL PROGRESS.

Carcinoma of the Colon: Resection: Cure.—M. Nicolaysen reports the case of a woman, aged 49 years, who, for a year, had suffered from constipation alternating with painful, bloody, and mucous stools. A tumor could be detected high up in the colon, which could be forced into the rectum by the expulsive efforts of the patient. The operation was performed in the following manner: after having forced the carcinomatous tumor into the rectum, the patient was chloroformed, the rectum washed out with carbolized water, the bladder emptied, and the tumor drawn outside of the anus. The left index finger was introduced into the intestinal canal 2½ cm. above the limits of the neoplasm and the walls of the colon, which at this level were perfectly healthy, pierced by a row of sutures extending completely around the bowel. The diseased portion was then excised 1 cm. below the sutures, which closed the tubes so well that only a single ligature was required. The edges of the wound were then united by sutures and the bowel released; it immediately retracted. The patient was cured in fifteen days, and no trace of the seat of operation could be detected in the rectum. The excised portion was 6.5 cm. long. The patient was in good health two months and a half after the operation.—*Nordiskt Medicinskt Arkiv*, 1882, No. 8.

Iodoform in Lupus.—Dr. Riehl (*Wiener Med. Wochenschrift*, 1881, xxxi. p. 534) has used this drug as a local application in lupus vulgaris with flattering success. In order to remove the epidermis and thus render the diseased tissues accessible to the action of iodoform, a fifty per cent. solution of caustic potash was applied to the skin after removal of all dirt and grease from the same by means of washing with soap and water. Left in contact with the skin a caustic solution of this strength in from one-half to two minutes caused transparency, swelling, and detachment of the epidermis. This effect produced, the excess of caustic potash was washed off with water, the surface thoroughly dried, and a layer of finely powdered iodoform from one to two millimetres in thickness was applied to the surface which had been denuded of epidermis. This, covered with cotton batting, retained in place by strips of sticking plaster, was left undisturbed for from five to eight days. In no case was there suppuration, and on removal of the dressing the iodoform was found embedded in the depressions due to the disappearance of diseased tissue. Adherent at some points, at others which were in process of cicatrization the iodoform was merely superimposed. The sound skin between the points of pathological infiltration was pale and soft, and the general swelling and rednesss of the parts had in great measure diminished. In severer cases, while there was never suppuration, two or three successive applications of this dressing were required before the pathological infiltration of the tissues disappeared. The application of iodoform to surfaces of skin denuded of epidermis, caused neither pain nor any disagreeable sensations. To do away with the pain necessary to the application of caustic potash, local anæsthesia may be used. The author has employed this dressing in twenty cases of lupus, and always with good result.—*Arch. of Derm.*, July, 1882.

Gonorrhœal Arthritis.—Prof. Peter pointed out a case at his clinic (*Gaz. des Hôp.*, June 17th) in illustration of the fact that in the so-called gonorrhœal rheumatism the joint is not the seat of the affection, but the adjoining white tissues or "tenosity;" and that consequently there is no complication from heart disease, while the prognosis is much more favorable. The gonorrhœal discharge exerts no specific effect in producing it, any genital irritation being competent to do this, acting through some ill-understood mechanism, as in profuse leucorrhœal discharge, or the sudden arrest of the menses. In this case abundant gonorrhœal discharge was present in a woman, and the left ankle-joint seemed to be the seat of an attack of acute rheumatism. This, however, was not the case, and the diagnosis was obtained by the mode of examining the joint. Feeling below the internal malleolus, great pain was produced; but palpation at the external part, or in front, or deeply behind under the tendo Achillis, gave rise to no abnormal sensibility. Returning again to the inner side, and examining methodically, it was found that pain really only existed in the direction of the sheath of the tendons which passed under the malleolus internus—there being therefore only a tenosity, easy to define. It is only very rarely indeed that the joint is implicated.—*Med. Times and Gaz.*, August 19, 1882.

Idiopathic Spasm of the Tongue.—The isolated independent spasm of the tongue belongs to the rarest forms of spasm. Under the name "aphthongic," Fleury described a singular neurosis in the hypoglossal region, in which each attempt at speaking called forth tonic and clonic spasms of the muscles of the tongue, which rendered articulation impossible. Berger, *Neurol. Centralbl.*, No. 3, 1882) has met with two cases, the first being that of a lady aged 28, neither nervous nor hysterical, in whom there appeared, during the last few years, whilst enjoying the best of health, a peculiar tension above the larynx, and a feeling of swelling in the tongue, followed after one or one and a half mintutes, by a rhythmical twitching of the tongue, which was propelled against the row of teeth at the rate of fifty or sixty a minute. During the attacks, which usually lasted from one to two minutes, speech was impossible. Other cephalic disturbances there were none, nor was there any anomaly either of the tongue or of the oral cavity. A course of baths in Landeck, and the use of iron spas, brough about a cure after some time. The second case was that of a man in whom, after his fortieth year (now two and a half years ago), the

tongue was periodically projected from the mouth with great rapidity and force, this happening sometimes several times in the week; at others, several times in the same day. The author assumes for both cases an irritable condition, either cortical or bulbar, of the hypoglossal nerve as the cause, and adds, as similar to the above, two observations which he has made on men aged 44 and 56, in whom there was spasm of the cremaster muscle, lasting two or three minutes, several times a day. Kissingen and Karlsbad waters cured the one case very nearly; in the second, the subcutaneous administration of atropine, and three weeks' galvanization (positive pole on the spinal cord, negative pole to the scrotum) effected a cure.—*London Med. Record*, August 15, 1882.

PITYRIASIS CIRCINATA ET MARGINATA.—EMILE VIDAL (*Ann. de Derm. et de Syph.*, 2 s., vol. iii.) describes a fungous parasite, which he claims to have discovered in this affection, and which he calls *microsporon anomœon* (*microsporon dispar*). Examined with an immersion objective, No. 10, Hartnack, epithelial scales from a patch of pityriasis circinata exhibit spores of a diameter of one micro-millimetre, many even smaller, larger spores being the exception, never exceeding one micro-millimetre in diameter. The principal characters of this fungus are: 1. The diminutive size of the spores, and their great variation in volume. 2. A circular arrangement in the epithelial cell. 3. The scarcity of chains of spores. 4. The absence, or, at least, great rarity of mycelium. The fungus affects the superficial and, particularly, the middle layers of the epidermis. It is to be observed more especially upon the face, beard, and neck. The hair escapes, and its follicle does not become inflamed. The clinical signs of the affection are described, and its differential dignosis with "pityriasis rosea, pityriasis versicolor, erythrasma, and trichophytosis circinata" indicated. Vidal has never seen the affection in persons of more than 40 years of age, and has never known it to spread by contagion. Its cure is easily effected by the use of ordinary antiparasitic remedies.—*Archives of Derm.*, July, 1882.

GASTRIC ULCER.—In the course of some experiments on the production of nephritis by the injection of cantharidin under the skin, AUFRECHT has made the remarkable discovery that ulceration of the stomach may result from these injections. After the subcutaneous injection of cantharidin, suspended in oil to lessen the local irritation, he found in guinea-pigs a large number of circumscribed changes in the mucous membrane of the stomach. These were at first regarded as merely hemorrhages, but on closer examination were found to be spots of loss of substance, the boundary of which projected above the level of the adjacent mucous membrane. These changes were especially conspicuous in the stomach of a rabbit, which died ten days after the injection of 2½ milligrammes of cantharidin. About fifteen small ulcers were found in the stomach, many of them with raised edges, and all filled with blood-clot. There were also six circular spots of a dull gray color, sharply limited, without any extravasation. A microscopical examination showed in the latter the following changes: the epithelium of the glands was paler and less granular than normal; between the glands was a clear amorphous material; the capillaries were distended with blood, whereas, elsewhere, they were empty. A similar change was found in the vicinity of the extravasations, and the glandular epithelium here presented irregularity. The extravasations were of uniform brownish-red blood, in which no intact blood corpuscles could be seen. There was no sharp limitation to the blood effused, such as might have been expected had the hemorrhage resulted from the rupture of one vessel. From these facts he concludes that the extravasation is the second stage in the process, consecutive to inflammation, which appears to be the first alteration. Aufrecht believes that these facts indicate that in man a similar sequence may obtain, and that ulcer of the stomach probably commences as inflammation, and not, as is commonly assumed, by hemorrhage.—*Lancet*, August 19, 1882.

NEW METHOD OF TREATMENT OF VARIOLA.—M. DREYFUS BRISAC has had an opportunity of testing the method of treatment of variola recommended by M. DUCASTEL, and has published his report on his results. The method consists in the administration of a mixture of ether and opium, with the separate use of perchloride of iron, alcohol, and ether, subcutaneously. He finds that it is best to omit the perchloride of iron, except in hemorrhagic cases, and that the ether injections sometimes prove irritating, but not sufficiently so to prevent their use. He believes that while the influence on the general disease is doubtful, this treatment does undoubtedly control the eruption.—*Gazette Hebd.*, Aug. 11, 1882.

SPONTANEOUS FALLING OFF OF THE NAILS IN ATAXIC PATIENTS.—This phenomenon, which is not mentioned by any of the classic authors, is, perhaps, not so rare as is supposed. One case of it is mentioned in M. Arloing's thesis, and M. PITRÉS has reported two cases in the *Progrès Médical*. In these two patients, both of whom had confirmed tabes, the nails of the great toes had come off spontaneously, without any trace of external violence. The loss of the nails was preceded for some weeks by a dull pain and a sensation of irritation in the corresponding toes, without the lightning pains being more acute than usual. There was neither suppuration nor ulceration apparent at the matrix of the nail. The nails were rapidly replaced by new nails of normal formation. It is probable that the disorder is connected with disturbances of nutrition depending upon medullary lesions, analogous to perforating ulcers, spontaneous fractures, and various eruptions. In these two cases, the repeated falling off of the nails can scarcely be attributed to external violence. A sufficiently violent wound to bring on detachment of the nail would certainly have attracted the attention of the patients at the moment of its production, and eventually produced severe pain.—*London Med. Record*, August 15, 1882.

GASTROSTOMY.—On the 21st ult. SIR WM. MACCORMAC performed this operation at Hackney, on a gentleman aged 55 years (a patient of Dr. Daly), who had malignant stricture of the œsophagus. The operation, as well as the subsequent dressings, was performed with the strictest antiseptic precautions. The procedure was divided into two stages, the stomach not being opened for fourteen days from the first operation. The temperature never rose above 98.6° or the pulse above 80. The patient, during the fortnight, was fed by the rectum, defibrinated bullock's blood being chiefly used for this purpose. The patient recovered without any unfavorable symptoms. He was up sixteen days after the operation. He is now fed through the opening in his stomach four times a day; he has a pint of milk, with a couple of eggs, or a pint of beef-tea or soup, at a time. He is gaining flesh and is in good spirits. Further details of this case will be published hereafter. —*Lancet*, August 19, 1882.

SYPHILIS OF THE HEART.—Only nineteen cases of this rare affection have been hitherto described. To these B. TEISSIER (*Annales de Derm. et de Syph.*, 2me ser. t. iii., No. 6) adds another, essentially as follows:

A prostitute, 27 years of age, in the third year of syphilis, which, however, had only manifested itself in the form of buccal mucous patches, was suddenly seized with dyspnœa, followed by asphyxia and death within twenty-four hours. The autopsy showed extensive involvement of the anterior walls of the right ventricle in its upper half, the muscular tissue of which seemed to have become entirely transformed. The thickness of the cardiac wall appeared about normal, but it seemed of a peculiar light gray color, and its consistence much firmer. Section showed numerous milk-white lentil-sized nodules, both in the cardiac walls and elsewhere. These presented a caseous appearance, but were in reality of quite firm consistence, showing no trace of softening even in the centre.

In addition to the interstitial myocarditis and the gummatous deposits, there were considerable vascular alterations in the form of peri-arteritis, endo-arteritis, etc.—*Archives of Dermatology*, July, 1882.

EXCISION OF THE PYLORUS.—DR. VAN KLEEF, of the Hopital de Calvaire, Maestricht, relates in the *Presse Méd. Belge*, July 23d, the case of a woman, aged 37, upon whom he performed excision of the pylorus on account of stenosis, supervening on ulcer of the stomach attended with severe hæmatemesis. She had become greatly reduced in strength, and for some time past had been fed by the rectum. The indurated pylorus, when removed, measured 4½ by 5 centimetres, and a quill could scarcely be introduced into its aperture. The stenosis was due to cicatricial tissue, no sign of carcinoma being present. The operation lasted two hours, and an hour or two elapsed before the patient began to awake from the anæsthetic condition. Her recovery from the state of anæmia was slow but progressive, and two months after the operation she was able to leave the hospital, weighing 39 kilogrammes. At the date of the report, about six months after the operation, she weighed 45 kilos.—*Med. Times and Gaz.*, August 12, 1882.

RELATION OF DIPHTHERIA TO SCARLATINA.—At the meeting of the Societé de Therapeutique, held June 28, M. BLEODEAU referred to an epidemic of scarlatina which he had recently witnessed, in which only two out of eleven cases showed any anginose symptoms. He uses this fact as an argument against the theory advanced by M. Archambault as to the identity of scarlatina and diphtheria.—*Journ. de Méd. de Paris*, Aug. 12, 1882.

THE AURICULAR VASO-DILATOR NERVES.—MM. DASTRE and MORAT give the following *résumé* of their experiments on the vaso-dilator nerves of the auricle.

1. The auricular vaso-dilator nerves arise in the cervical region of the spinal cord.

2. On leaving the cord these nerves are contained in the anterior roots of the corresponding spinal nerves; they are especially to be found in the eighth cervical and first dorsal pairs of nerves.

3. After joining the mixed trunk of the spinal nerves, they reach the sympathetic at the level of the first thoracic ganglion through the communicating fibres.

In a word, the auricular vaso-dilator nerves have their origin in the cord, pass out through the anterior spinal roots to join the cervical sympathetic and unite with the dilators of the bucco-facial region previously described.—*Rev. Scientifique*, August 19, 1882.

FLOATING KIDNEY.—Having examined 1,422 patients (1,030 females, 392 males) at a watering-place in Galicia, the author (*Przeglad Lekarski*, 1882, Nos. 1 and 2) found in 35 subjects (32 females, 3 males) floating kidneys. In 19 patients (2 males, 17 females, 9 of whom were pluriparæ, 8 multiparæ) the right kidney floated. In 11 patients (1 male, 4 multiparæ, 6 pluriparæ) the left kidney was movable. In 5 pluriparæ, both kidneys floated. Comparing his figures with those of Landau, Dr. SKORCZEWSKI concludes that the affection under consideration is far more common than it is usually supposed, and that physicians too often overlook its existence. He supports this statement by the fact that the 35 patients were sent on account of all possible diseases except wandering kidneys. On the subject of etiology, he differs from Landau, who asserts that a pendulous abdomen prediposes to renal displacement. According to Dr. Skórczewski, such displacement depends chiefly upon on the disappearance of circumrenal fat, on atony of tissues, subsequent to acute febrile diseases, and on pressure of some hypertrophied abdominal viscera. In the author's cases, there was very often observed coexistence of floating kidneys with malarial hypertrophy of the spleen. Such coexistence was noted in 13 out of 16 cases of the left displacement, and in 13 out of 24 cases of the right; and the author emphatically recommends examination of the kidneys in all malarial affections.—*London Med. Record*, August 15, 1882.

MEMBRANOUS DYSMENORRHŒA.—DR. LUTAND concludes from a study of this subject:

1. That membranous dysmenorrhœa consists of an exfoliation of the hypertrophied uterine mucous membrane.

2. The expulsion of the mucous membrane does not take place each month; several months may elapse between each expulsion.

3. This affection is quite common in virgins and can, therefore, not be regarded as the result of conception.

4. It nearly always causes sterility.—*Ann. de Gynecol.*, August, 1882.

NEW REMEDY FOR LEPROSY.—DR. E. WESTLUND (*Transact. of Soc. of Physicians in Upsala, Sweden*), starting with the supposition that leprosy might be due to micro-organisms, tried in three cases salicylate of soda with marked effect. The first case was that of a man suffering in a high degree from lepra tuberculosa. Tubercles varying in size from a pea to a hazel-nut were found in the skin of the face, the extremities, the abdomen, the scrotum, and in the throat. The hoarseness of the voice indicated their presence in the larynx. The muscles of the hands were atrophic; the eyebrows had been lost; the hair on the head was thin and dry; the nails thick, curved, and fissured. No ulcerating tubercles. He was advised to take one gram (15 grains) of sodium salicylate five times a day in a tablespoonful of water. The patient wrote after some months to report that he was perfectly cured.

The two other cases were yet under treatment, but had improved very considerably when they were last seen.—*Archives of Dermatology*, July, 1882.

ERYSIPELATOUS ERUPTIONS CAUSED BY TINCTURE OF ARNICA.—In *L'Union Médicale*, for August 17, M. SAISSUS reports two cases in which free external use of tincture of arnica produced an erysipelatous eruption. Both cases recovered under the use of emollient applications and purgatives.

LUPUS.—The following conclusions are given by DR. RAUDNITZ (*Viertelj. f. Derm. u. Syph.*, 1882), as the result of the statistical examination of 209 cases of lupus. Neither anatomically nor clinically can a difference between scrofulous and idiopathic lupus be made out, the disease appearing in the same form in individuals already scrofulous, and in those entirely healthy.

A combination with inherited tuberculosis is only discernible in from ten to fifteen per cent. of all cases. The abscesses of the lymphatic glands so frequently met with in scrofula are almost never found in lupus. A cotemporaneous manifestation of lupus in blood relations is seen only in the rarest instances, and hereditary transmission of lupus from parents to children perhaps never takes place. The infrequency of association between lupus and pulmonary tuberculosis decidedly speaks against the identity of these affections. On the other hand the facts, that in at least thirty per cent. of the cases lupus was developed upon or only in the neighborhood of scrofulous cicatrices, or upon mucous membranes already changed by catarrhal processes; that in twelve cases, injury, and in eight cases, local attacks of erysipelas were given as exciting causes, would indicate that lupus is often due to a localized specific predisposition, the nature of which is entirely hypothetical. At all events the small proportion of cases, seventeen in number, in which lupus was found in combination with often trivial affections of the skin, seems to contradict the assumption that in lupus we have to do with a generalized predisposition of the skin to pathological changes.—*Arch. of Derm.*, July, 1882.

INTERNAL URETHROTOMY.—PROF. T. F. KOSINSKI, in a very interesting article based on his own 103 cases (Maisonneuve's) of internal urethrotomy (*Gazeta Lekarska*, 1881, Nos. 78–80), points out the advantages of this treatment in urethral stricture. The operation he regards as extremely simple and easy, and the injury caused by Maisonneuve's instrument as very slight and entirely free from any danger. The wound heals rapidly, and the subsequent introduction of bougies, practised during certain (considerably long) periods, successfully completes the treatment. The author's cases were all severe; some of them were complicated by urethral and vesical fistulæ, and the operation was resorted to only after gradual and slow dilatation had utterly failed to make the stricture permeable. Nevertheless, in all 103 cases, cure very rapidly followed. All patients got up in a few days after the operations, and, two weeks later, they returned to their occupations. Fistulæ very often closed spontaneously after the urethra had recovered its lumen. The author advises to split the anterior wall of the meatus, following the median line. After the operation, he leaves a soft elastic catheter *à demeure* for twenty-four to thirty-six hours; afterwards, the patient voids urine by the natural passage. In one-third of all the cases, on the third or fourth day after the operation, there was a considerable rise of temperature (to 102° to 104° Fahr.), followed by profuse perspiration; the further course did not show anything peculiar.—*London Med. Record*, August 15, 1882.

TREATMENT OF ALBUMINURIA WITH FUCHSIN.—Feltz and Bouchet (*Deutsch Med. Woch.*, 1879) first proposed this remedy in pills of three grains per day for chronic parenchymatous nephritis. Later, Professor di Renzi, of Genoa (*Virchow's Archiv*, vol. lxxx.), reported more fully on the use of the remedy. He gives it in pills of 2½ centigrammes (3.8 grains) each, beginning with two pills and increasing to ten per day. Under this treatment he found a marked decrease in the amounts of albumen and mucus. The drug causes distinct coloration of the urine, and if this effect is not produced, it is an evidence that the drug is not absorbed, and its use should be discontinued. Now, Dochmann (*Vratsch*), having made extensive use of fuchsin, draws the following conclusions:

1. In many cases of albuminuria, the amount of albumen in the urine is decreased under the use of fuchsin.

2. In other cases, the decrease is only apparent, as the albumen in such urine is converted into pepton more rapidly than usual.

3. The coloration of the urine by the drug bears no positive relation to the decrease in the amount of albumen.

4. Arsenic-free fuchsin can be given for a long while to adults without injury in doses of from one to two grammes per day.—*Physician and Surgeon*, Sept. 1882.

AMPUTATION OF THE TONGUE BY MEANS OF THE THERMO-CAUTERY.—In all important operations on the tongue, it is essential, 1st, that all the diseased tissue should be removed; 2d, danger of hemorrhage should be avoided; and, 3d, the entrance of blood into the air passages prevented. LANGENBECK believes that, whatever the seat of the disease, all these conditions may be fulfilled by combining his method with that of Billroth, and division of the lower jaw. From 1875 to 1881, Langenbeck made nineteen extirpations of the tongue; of these, one was operated on by the Regnoli-Billroth method, and the others by his own plan. Of these six died, and among them the case operated on by the Billroth method. Since then he has done the operation seven times with the thermo-cautery; he does not, however, state with what result. The preliminary ligation of the lingual artery is recommended.—*Journ. de Méd. de Paris*, July 22, 1882.

OSTEOTOMY—Fourteen cases in which osteotomy was done for the relief of rachitic curvatures of the limbs, for genu valgum, for ankylosis of the hip, and for complicated or viciously united fractures, serve as the basis for a recent communication by M. JULES BOECKEL, of Strasbourg, to the *Revue de Chirurgie*, No. 6, p. 461. In conneetion with these, he considers, also, nine cases communicated to the Society of Surgery, of Paris, making a total of twenty-three recent cases to be added to his previous reports on this subject. In all these cases a cure resulted. Of the whole number seven were adults of from fifteen to twenty-eight years; and fifteen were children, the youngest of whom was eighteen months, and the eldest eight years. In sixteen instances suppuration was wholly wanting, and the cases were healed with one, two, and three dressings; slight suppuration occurred in six cases; in one only was it abundant. The operation was complicated in this case by a phlegmonous erysipelas, which necessitated repeated incisions. The time necessary for consolidation to be accomplished varied from a minimum of twenty-one and twenty-eight days, to a maximum of two and three months. The final result has been most satisfactory in all the cases. A permanent cure was determined at the end of months and years—seven years in the cases first operated upon. In the opinion of the author, osteotomy, done with Listerian precautions, is, in children, so simple and harmless an operation, that their stay in hospital is unnecessary. For two years he has sent such patients to their homes, after operating, without ever having had to regret it. For the relief of genu valgum he adopts exclusively the method of Macewen.—*Annals of Anatomy and Surgery*, September, 1882.

ABDOMINAL DRAINAGE.—The following new method of drainage after ovariotomy, adopted by Dr. Kehrer (*Centralblatt für Gynecologie*, 1882), is worthy of more than a passing notice. He inserted into the cavity of the abdomen three rubber tubes into which he introduced disinfected wicks of the thickness of the little finger. The external bandage was soon wet through by the secretion, and had to be changed three times during the first two days, after which it ceased altogether. —*Canada Lancet*, September, 1882.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE, ... $5.00.
SINGLE COPIES, ... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made at the risk of the publishers, by forwarding in REGISTERED letters.

Address, HENRY C. LEA'S SON & CO.,
NOS. 706 & 708 SANSOM STREET,
PHILADELPHIA, PA.

SATURDAY, SEPTEMBER 9, 1882.

THE MICROSCOPICAL EXAMINATION OF GUITEAU'S BRAIN.

WE present to our readers in this issue the report of the microscopists, to whom was assigned the important task of the microscopical examination of Guiteau's brain. The gentlemen who have performed this duty are too well known as experts in this department of science to require a word of support or vindication from us. We take pleasure in the exhibition which the report makes of a truly scientific and logical spirit. The subject has been approached in a judicial temper, the examination has been made without prejudice, and the conclusions are stated with fairness.

In our remarks on the previous report of the autopsy, we maintained that there was nothing in the gross appearances to justify the theory of irresponsible mental unsoundness. But we also reserved a final judgment until the results of the microscopical examination were placed before us. We have now a demonstration of great accuracy and minuteness, involving structures not recognizable by unaided vision. With the new light thus thrown on the case what opinions must now be formed? The organic substratum on which the mental operations are conducted being thus exposed, what conclusions must be settled upon regarding the mental condition of Guiteau?

The changes discovered were chiefly in the vessels, the perivascular lymph-spaces, the neuroglia, and the cells. We will not reproduce here the details, since our readers can follow them leisurely in the report, assisted by the accompanying figures. Our function, more especially, is to interpret the significance of the pathological changes, and trace, if we can, the relation between them and the mental condition. At the outset we are debarred from throwing any doubts on the genuineness of the microscopical demonstration. Post-mortem changes, and alterations due to the methods of preparation pursued, are often alleged against the results of such minute researches. That this distrust of microscopical work is abundantly well founded, is proved by the sad mistakes of the most eminent workers. But in this instance there are means of control. Healthy and diseased structures being subjected to the same methods, the results of comparison can be relied on.

Accepting therefore the observations of the microscopists making this report, as accurate, the first conclusion we reach is—that the changes for the most part are recent in origin. Whilst numerous lymphoid cells migrating from the vessels, distended the perivascular lymph-spaces, and the pericellular spaces, the anatomical elements—the nerve corpuscle, and the neuroglia cell—were generally preserved, although in some instances they were destroyed. Masses of pigment, remains of red corpuscles, in some places filled the lymph-spaces, but generally only lymphoid cells were present. In some instances the vessel walls presented the appearances of granular degeneration, but more frequently only the endothelium exhibited this change. As regards the white fibres, there were seen, in various places, numerous lymphoid cells, on and between the separate bundles, resembling in appearance the changes in the optic nerve in descending neuritis. The above-mentioned alterations of structure in the corpus striatum were found here and there disseminated "among tissues in which nothing distinctly abnormal could be made out."

From the point of view of the mental condition, the greatest interest attaches to the examination of the different layers of the cortex. Some thinning of the first layer was noted, and more or less cellular hyperplasia. Some granular degeneration of the walls of the vessels was discovered in the second, fourth, and fifth layers. In this region, also, there was more or less pigmentation of the cells, and lymphoid cells were contained in the intercellular spaces, but the anatomical elements were for the most part present. Atrophic degeneration to any marked extent, we do not find to have taken place, notwithstanding we admit the existence of the vacuoles observed at various points. The changes just referred to were most marked in the anterior portion of the gray cerebral matter, but were generally diffused, although less in amount, as the examination extended through the cerebral cortex posteriorly.

As the anatomical elements were, for the most part, in their usual form and position, although somewhat changed by pigmentation, by the presence

of lymphoid cells, etc., and as there were only in the dura mater but doubtful evidences of any inflammatory action of a chronic type, we are led to the conclusion above expressed, that the changes revealed by the microscope, although, as stated in the report, chronic in type, are recent in origin. Such an amount of granular degeneration of the vessels as here described may be effected in the brief space of time in which such changes are wrought in acute phosphorus poisoning.

Quite apart from the time in which these structural changes have occurred, is the question of their influence on the mental state. As a marked degree of double optic neuritis may coexist with preservation of quite sufficient acuteness of vision for all ordinary purposes, so considerable changes of the organic substratum may coincide with fairly good intellectual powers. In the case of Guiteau, some changes are discovered, on microscopical examination, but do they necessarily imply a degree of mental weakness incapable of distinguishing between right and wrong? We hold that they do not. Furthermore, these changes are we believe recent in origin, therefore they hardly involve the question of his moral responsibility anterior and up to the commission of his crime. They constitute the initial stage of a malady, which, in its fullest development, is known as dementia paralytica or an allied disease; the early symptoms of which disorder correspond closely with the mental condition of Guiteau during the past year.

As, however, extensive lesions of the brain are not incompatible with a normal exercise of the intellectual faculties, it follows that the mere structural changes of the organic substratum, cannot be safely interpreted alone. The clinical history must be studied in connection with the alterations in the cerebral structures. If we pursue this logical course, we can be conducted but to one conclusion: that, although Guiteau was not strictly normal in respect to the condition of the organic substratum of the mind, and in respect to its symptomatic expression, he was, nevertheless, a responsible agent, in that he had a clear conception of the distinction between right and wrong, and realized the nature of the crime and its punishment.

There is, therefore, in the microscopical revelations, no reason for changing the opinion which we originally expressed, that Guiteau, an abnormal character, justly suffered the penalty of the law for the high crime he had committed.

PROFESSOR ESMARCH ON THE CASE OF PRESIDENT GARFIELD.

THE time has almost arrived when a reply to an attack on the course pursued by President Garfield's surgeons will, by mere iteration, have lost its interest to the profession, the great majority of whose members have long since come to a final—and a favorable—conclusion upon the subject. The adverse criticism in this country has emanated, almost without exception, from writers whose lack of surgical eminence on the one hand, and of personal familiarity with the case on the other, has greatly weakened or discredited most of their assertions.

The former of these disqualifications cannot, however, be said to apply to Professor Esmarch, who has delivered a lecture upon the subject, and has concluded that, if no search had been made for the ball, and the wound had been dressed aseptically, the patient would have been alive now.

He reaches this sweeping conclusion by the following steps, which we may venture to criticise as we mention, beginning with his statement that the wound was not in itself absolutely fatal. Upon such a question the dictum of no one man can be accepted as final, and even Prof. Esmarch's reputation will not support him against the united experience of the profession. He was of course familiar with the character of the wound of the vertebra, and he apparently does not question the probability that the splenic artery was injured either by the bullet or by a splinter of bone, although he says that this would not have led to the formation of a false aneurism, except for the establishment of "putrid suppuration." Until he can point to a case of perforating gunshot wound of the body of a vertebra followed by recovery, and can at the same time explain why an arteritis excited by injury or by the presence of foreign particles is not competent to give rise to a false aneurism, or can give reasons for believing a rupture of the splenic artery to be a non-fatal accident, we must take the liberty of differing with him on this first and most important point.

His subsequent argument rests upon the assumption that death was due to this "septic suppuration," to which he attributes the splenic aneurism, and that the formation of unhealthy or poisonous pus, was, itself, a direct result of the "repeated probing and examination of the wound with instruments and fingers not rendered aseptic; the failure to dress the wound aseptically; the syringing out of the wound with fluids not sufficiently antiseptic; and the failure to give a complete vent to the 'bagging' pus."

These statements are not in consonance with the facts of the case, and illustrate the impropriety of attempting to criticise a course of treatment the details of which have never been authoritatively set forth, owing to the interruption in the preparation of the surgical history of the case, caused by the severe illness of Dr. Woodward, to whom this task was assigned. An examination was made immediately after the accident, at the spot where it

occurred, and again, on the evening of the same day, when the President was apparently sinking from the effects of internal hemorrhage. These were, of course, absolutely required, and as far as regards the first one, at least, were made under circumstances which did not admit of antiseptic precautions. Subsequently, until the occurrence of suppuration, no further interference with the wound took place. Professor Esmarch has probably been misled in this respect, by the inadvertent statement of Dr. Bliss, in his published account of the case, that the consultants on the occasion of their first visit, introduced probes and flexible bougies into the wound. This error was not committed, and we have the highest authority for stating that no such examination was made then, or at any subsequent time, although the so-called "neglect" to explore the wound, has been made the basis of equally severe—and equally unjust—criticism on this side of the Atlantic. Dr. Bliss has since pointed out that his mistake was due to the hasty preparation of his paper, from memory and without reference to notes. It should be remembered that Professor Esmarch's hypothesis, that the patient would have been benefited if "*no search*" had been made for the ball, was advanced with a full knowledge of the results of the autopsy. It is hardly to be believed that he or any other experienced surgeon would have felt justified on the first examination in entirely refraining from exploration, or would have expressed any such ante-mortem opinion.

It is not true that the wound was not dressed aseptically, or that it was not syringed out with antiseptic fluids. Whether it was made completely "aseptic" in the absolute sense in which Prof. Esmarch uses that term, is another question, but no practical surgeon can fail to understand the almost insuperable difficulties which stood in the way. A wound, contused and lacerated like all gunshot injuries, splintering bone, passing through a dense fascia like that covering the psoas muscle, through muscular fibres running at right angles and tending to close over it, and again through bony structures, opening venous sinuses, and forcing fragments of a vertebra into surrounding soft parts, is not well situated for the application of Listerism. Admitting as an axiom that all wounds *should* be rendered aseptic, it by no means follows that all wounds *can* be. Lister himself does not claim that.

Still we are authoritatively informed that what could be done in this direction was done, and that none of the precautions dictated by modern antiseptic surgery were omitted; certainly if dressing the wound under carbolic spray, washing it out with carbolated water and with permanganate of potassium, employing antiseptic gauze and other dressings, and disinfecting all objects brought in contact with it, constitute "asepticism," that condition was attained in the President's case.

As to the alleged failure to give vent to the pus, the history of the case and the post-mortem examination both demonstrate that the incisions, which were promptly made upon the earliest evidence of pus accumulation, were well planned, and that drainage was thorough and complete. The first operation was done within a few hours after the second visit of the consulting surgeons; the second operation laid open the abdominal parietes and the post-peritoneal lumbar space. That these incisions effected the desired object is conclusively shown by the absence at the autopsy of any pus collections along the track of the wound or in its vicinity.

Professor Esmarch's deserved eminence as a surgeon will give his utterances upon this, as upon all other surgical topics, wide-spread circulation, but it is not sufficient to disguise the fact that, arguing from incorrect and insufficient premises, he has reflected most unjustly upon some of his surgical peers in this country.

The mere fact that, with no precaution to verify the theories as to the details of the treatment upon which his entire argument is founded, he has voluntarily assumed the position of a critic and a detractor is of itself sufficient to take from his utterances much of their weight, and certainly will not add to his professional reputation.

We have never hesitated, since the publication of the autopsy, when it first seemed proper to discuss the subject, freely to express an opinion that the course pursued by the attending surgeons was deserving of praise and support, while that of their self-appointed critics was equally to be condemned as both unethical and unreasonable. We see nothing in the report of Professor Esmarch's lecture to cause us to change either of these opinions.

THE RELATIVE CURABILITY OF EPILEPSY AT SALPETRIERE.

DR. FERRAND has taken the above topic for the subject of his thesis (*Thèse de Paris*). The observations were made at the great hospital for the chronic insane and epileptics, under the direction of Dr. Legrand, on eighty-nine insane or idiotic epileptics. They were treated methodically with bromide of potassium, with the following result: Twelve cases were decidedly benefited, fifty-one were improved, sixteen were slightly benefited, and only ten received no benefit whatever. These figures are certainly encouraging when we remember the helpless character of these subjects.

Dr. Ferrand strongly insists on the mode of administration as an important factor in the results. In commencing the treatment, he gives two or three grammes (31 or 46 grains) or more daily, and in-

creases the quantity by fifty centigrammes (8 grains) every fifteen days or every month, until the daily quantity reaches, for women, five or six grammes, and for men six or eight grammes. Ferrand strongly criticises the method of Nothnagel and Rossbach, who advise that the treatment begin with a daily dose of five grammes (about 80 grains), and this be increased until ten, fifteen, or twenty grammes are given, a quantity that must produce the most pitiable effects. He commends the plan at present pursued by Dr. Legrand, which is as follows: After the attacks are suspended for one year by the administration of the bromide, as above suggested, it is given six days in the week; after fifteen months, five days; after eighteen months, four days; and after two years, three days.

Does bromide of potassium ever cure epilepsy? Opinions differ. Dr. Ferrand thinks that, administered systematically and perseveringly, all the epileptic phenomena may be entirely suspended. Aug. Voisin thinks that the curability of some cases is absolutely assured. Although Dr. Ferrand is less sanguine, and holds that the apparent cures were examples of epileptiform seizures, due to alcoholism, syphilis, plumbism, etc., he finds that many of the accompanying troubles are much modified, such as the nervous state, maniacal delirium, and the insane impulse, all of which are calmed by bromide. It exercises, too, a happy influence on the intellectual troubles. Epileptic mania is extremely improved. The nocturnal incontinence of urine is arrested by it, as also the aura; but the vertigo resists longer than any other symptom.

Bromide is eliminated by the sweat-glands, and free bromine, disengaged, excites different kinds of eruptions—acne, erythema—which sometimes give rise to unhealthy ulcers, urticaria, and eczema. Acne may be prevented by the simultaneous administration of arsenic, but ulcerations require the suspension of the remedy. The most frequent ill-results of improper methods of administration are headache, somnolence, impaired locomotion, gastric irritability, constipation, anæmia, feebleness, etc. Dr. Ferrand makes no mention of the mental disorders which have been observed in this country from the use of large doses of bromide of potassium.

IPECACUANHA IN DYSENTERY.

An increasing professional experience in the use of ipecacuanha in dysentery, amply confirms the original statements as to its very special value. There is, however, a singular lack of appreciation of its curative effects, and an unwillingness on the part of many physicians to give the remedy in sufficient quantity.

To cure acute dysentery with ipecac, its purgative effects must be induced.

To develop the cathartic action of ipecac, it must be taken in quantity.

It has been found that from one scruple to one drachm, every four hours, until the characteristic stools are produced, is the amount necessary. How to secure the retention of this quantity by the stomach is a vexatious problem. Combination with aromatic powder sometimes suffices, and this should not be neglected in any case. The conjoint administration of carbolic acid and bismuth, will diminish the irritability of the stomach. The powder is best swallowed mixed in milk; a mustard plaster should be previously applied to the epigastrium, and some bits of ice allowed to melt on the tongue until the nausea ceases. If rejected several times, presently tolerance is established, when the maximum doses will be retained. When "the ipecac stools," as their peculiarity entitles them to be called, are passed, astringents complete the cure.

CHLORATE OF POTASSIUM IN EPITHELIOMA.

In an elaborate article on the various modes of treating epithelioma of the face, Prof. Terrillon refers to the good effects of chlorate of potassium in the more benign cases. Although he proposes other expedients, he recognizes the utility of the chlorate in many instances.

NAPELLINE.

We have already given an account of this rediscovered alkaloid—for, as we pointed out, it had been isolated and its chemical properties defined, long before Duquesnel had resurrected it from the grave of forgotten facts. Under the stimulus of new investigations, its properties are becoming better known, and it excites the interest alike of the pharmacologist and the practical physician.

Napelline differs from aconitine—its associated alkaloid—in these respects: it is not crystallizable; it is very soluble, and it possesses properties in some degree peculiar to itself. It has a distinct soporific action, compared by Laborde to that of narceine, and it acts like aconitine in lessening the sensibility of the sensory nerves. It may be administered, therefore, in a great many painful affections, in which insomnia is a pronounced feature. Dumontpallier, who has employed napelline in his hospital practice, finds it effective in the treatment of facial, sciatic, and intercostal neuralgia.

As napelline is very soluble and diffusible, it is suitable for hypodermatic injection. Laborde has administered it in the dose of three centigrammes —about one-sixth of a grain. It is, therefore, much less powerful than aconitine.

Should future trials confirm those above referred to, napelline will occupy an important position as a remedy.

SPECIAL ARTICLE.

OFFICIAL.

REPORT OF THE MICROSCOPICAL EXAMINATION OF THE BRAIN OF CHARLES J. GUITEAU,

WHO DIED BY HANGING JUNE 30, 1882, AT THE UNITED STATES JAIL, WASHINGTON, D. C., IN EXECUTION OF JUDICIAL SENTENCE.

D. S. LAMB, M.D.

SIR: The committee of three whom you, with the assent of Rev. Dr. W. W. Hicks, requested to make a careful microscopical examination of sections from the brain, dura mater, and lung of the late Charles J. Guiteau, and to report the conditions found to be present, have completed their investigation, and have agreed upon the following:

REPORT.

Thin sections, prepared by Dr. J. C. McConnell of the Army Medical Museum, from the lung, dura mater, and brain, were submitted to your committee for their inspection.

The committee regret that the preparations presented did not more completely represent the whole brain and its membranes.

The Lung.—The sections of lung were from the left upper lobe. Their appearances were common to miliary tubercle. Some of the minute nodules consisted of aggregations of recently formed miliary tubercles in which giant-cells were quite distinct. Others contained older foci of similar aggregations which had undergone corneous degeneration.

Considerable pigmentation of the pulmonary parenchyma, very like that of anthracosis, was also to be seen.

Dura Mater.—The sections of dura mater were from the region of the middle meningeal artery. They showed but few, if any, signs of inflammatory action, and there was not much thickening evident.

Brain.—The brain sections comprised the following series, viz., sections from two portions of the *corpus striatum*, marked respectively, corpus striatum 1, corpus striatum 2; and sections from four portions of the gray matter of the convexity or cortex of the cerebrum, labelled respectively frontal region, convexity 1, convexity 2, convexity 3. Those from the frontal region were probably from the superior frontal convolution, whilst those marked convexity 1, 2, and 3, were cut respectively from the ascending frontal, the ascending parietal, and the superior parietal convolutions bordering upon the median longitudinal fissure, but the committee were not informed from which hemisphere.

A close examination of these sections, under a high power of the microscope, revealed the lesions noted below:

Corpus Striatum 1.—Not a few of the bloodvessels, particularly capillaries and venules, were decidedly abnormal. Their perivascular lymph spaces were often more or less completely filled with masses of yellowish-brown pigment granules, which appeared to be the degenerated remains of old blood extravasations (see *d*, figure 1).

FIG. 1.

In areas very numerous but mainly limited to the gray or ganglionic substance, the capillary blood vessels presented their walls in a state of granular degeneration (such as that indicated at *k*, figure 7). Sometimes these granules were limited within the endothelial cells, constituting the wall of the capillary, but often they were found for a considerable distance completely encircling the vessel.

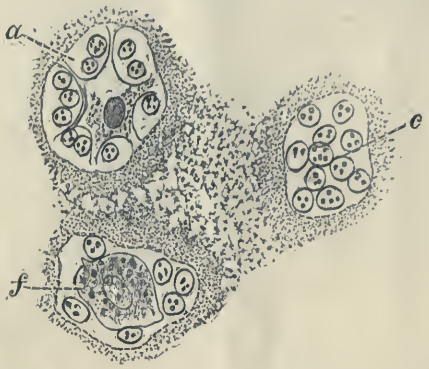
The lumen of the bloodvessels was usually void of blood corpuscles, and was patulous. A small number of very minute recent hemorrhages were to be seen.

In the gray or ganglionic matter of these sections were quite numerous areas, in which alterations of the neuroglia and of the ganglionic nerve corpuscles were very plainly visible. In them the pericellular lymph spaces were much crowded with lymphoid elements (*d*, *e*, *f*, figure 2). In some such areas, as at *e*, the whole space seemed to be occupied by collections of such cells, no trace of the neuroglia cell or nerve corpuscle remaining. Most frequently, however, neither the encompassed nerve corpuscle nor the neuroglia cell was destroyed. On the contrary, their nuclei and branched processes were generally distinct. Yet in many cases the body of the cells was extensively tinged with a yellowish-brown pigment, and, in a smaller number of cells, the presence of well-defined, dark granules in the cell-body was sufficient to mask entirely the nucleus, if any existed, Moreover, in the latter case, the cell processes were sometimes much less numerous than normal, and the body of the cell was not so angular (something of this condition is represented at *f*, figure 2).

Corpus Striatum 2.—In these sections, the neuroglia and nerve corpuscles were found to be in much the same condition as above noted.

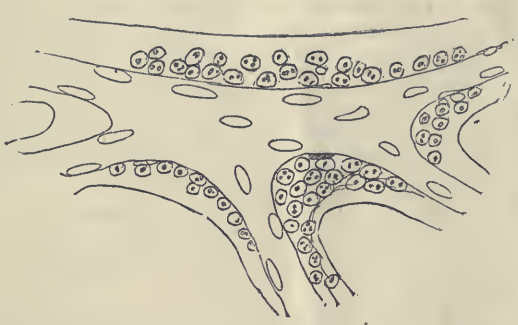
In a general way it may be stated that the cellular hyperplasia or cell multiplication was more marked than in No. 1.

FIG. 2.



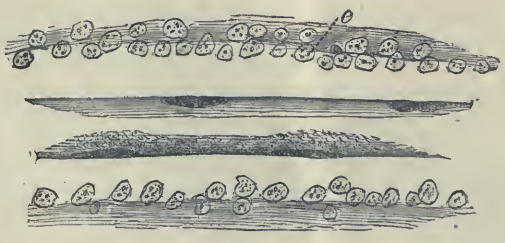
With respect to the lesions of the bloodvessels, two departures from health were noteworthy. Instead of those lesions consisting of the remains, in the perivascular lymph spaces, of blood extravasa-

FIG. 3.



tions, as in the first sections examined, these spaces at points along the course of the vessel were often found crowded with lymphoid elements. In some instances, these white cells were clustered closely around and adherent to the wall of the vessel upon its exterior, and often most abundantly aggregated in the immediate vicinity of a bifurcation (see figure 3). In others the cells were closely packed together

FIG. 4.



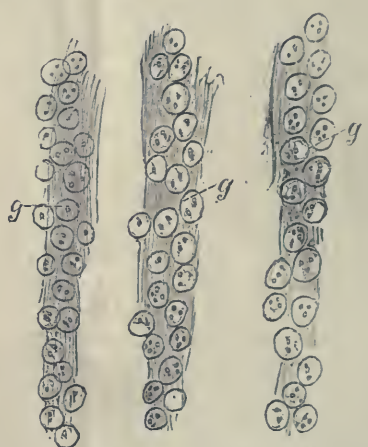
upon the external wall of the perivascular lymph space and slightly infiltrated the adjacent neuroglia (see *e*, figure 4).

In the white fibrous nerve substance there were isolated bundles of nerve fibres and collections of such bundles (see *f*, figure 5, low power, and *g*,

FIG. 5.

figure 6, high power), easily distinguished from the others by the presence, in greatly increased numbers, of cell elements upon and between them. Under a high power of the microscope, these elements were found to be outside the capillary bloodvessels, and to occupy the same relation to the nerve bundles and to the vessels, and to present the same general microscopic picture as that seen in longitudinal sections of the optic nerve in a descending optic neuritis.

FIG. 6.



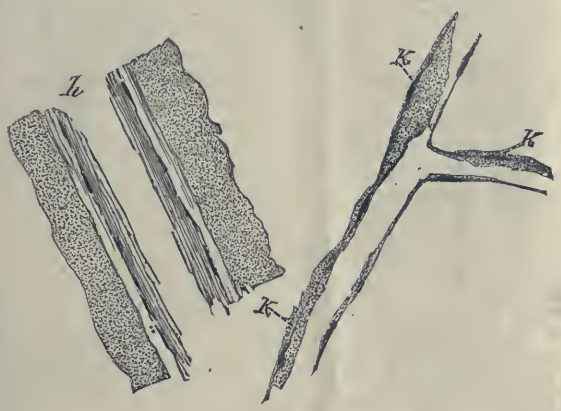
The areas of diseased structures above mentioned were more or less diffusedly scattered among tissues in which nothing distinctly abnormal could be made out.

Cerebral Cortex. Frontal region.—The first layer seemed to be thinned almost to nothing in spots at the convexity of the convolution. The depths corresponding to these spots were, perhaps, a little more hypercellular than other portions. In the second, fourth, and fifth layers, especially in the two latter, the bloodvessels presented, in a marked degree, degenerations similar to those remarked in the corpus striatum (see *h*, *k*, figure 7).

In the second, fourth, and fifth layers, the pericellular spaces, both of the neuroglia cells and of

the ganglionic corpuscles were more or less filled with lymphoid cells. In these layers, some ganglion nerve cells were also quite freely pigmented. Sometimes one-half the body of the cell was densely packed with pigmented granules to such an extent as to veil the nucleus, but the latter as well as the enclosed nucleolus even then could generally be discerned, although with difficulty.

FIG. 7.



This cellular hyperplasia was much more marked in the fourth and fifth layers than elsewhere, and was pretty uniform throughout them, yet even here there was an obvious tendency to distribution *en plaques*.

In the subjacent white nerve fibrous substance, the vessels were also sometimes slightly altered, and a few examples of cellular hyperplasia along the nerve bundles, much as was described for the corpus striatum, were rarely seen.

But few recent hemorrhages were visible in the sections examined.

Covexity Nos. 1, 2, 3.—The same abnormal appearances were remarked in all these sections, varying only in degree. It is sufficient to state that they were usually identical with those noted in sections from the frontal region, the only difference worth mentioning being the fact that the areas in which the vessels offered a granular degeneration were much less numerous and extensive than in the frontal region.

In the foregoing report it is to be assumed that the structures not specially mentioned were found in a condition so nearly normal as to call for no remark.

It should be stated, however, that in these various brain sections numerous so-called minute vacuoles were found. Whether these forms were real cavities or were transparent, highly refracting bodies of a definite constitution which was not revealed by the method of preparation, the committee do not undertake to say. Neither do they, in view of the widespread difference of opinion among observers, feel warranted in expressing a positive opinion as to whether or not these so-called vacuoles are to be regarded as post-mortem changes.

As bearing somewhat against the assumption of a post mortem origin for such appearances in general, the following facts, besides many other considerations, may be referred to:

1st. They are not constantly found in brains which have been obtained thirty-six and forty-eight hours after death, long after decomposition has set in.

2d. They have not infrequently been found in brains of animals killed for the purpose of experiment, when the nervous tissue has been instantly subjected to the action of the most perfect preservative fluids.

3d. They have been met with when the brain substance has been examined perfectly fresh.

4th. If they are the result of post-mortem change, they should not be met with immediately after death, but should appear and increase in number as decomposition advances. Yet no such relation to the time of death and state of decomposition has been observed for them.

In estimating the significance of these vacuoles in Guiteau's brain, it should be remembered that the specimens were obtained and submitted to the action of the preservative agents not more than five or six hours after death, an early period rarely possible with human subjects; that the microscope showed the elements of the brain well preserved in other respects; that in some brains examined forty-eight hours after death these appearances are absent, and in others they are often less numerous than they were found to be in this particular brain; finally, that they were associated with abnormal conditions of the bloodvessels and of the cellular elements of the brain.

In conclusion, your Committee have no hesitation whatever in affirming the existence of unquestionable evidence of decided chronic disease of the minute bloodvessels in numerous minute diffused areas, accompanied by alterations of the cellular elements in the specimens of brain submitted for their examination. Whilst the lesions found were most marked in the corpus striatum and in the frontal region of the cerebral cortex, yet they very diffusely pervaded all portions of the brain which the sections represented.

They are of the opinion that all of the lesions to be recognized in the sections placed in their hands have been pointed out in the foregoing report. They regret that it has not been possible to subject the tissues to all the tests which might determine the nature beyond a peradventure of the so-called vacuoles referred to.

They have not been called upon to pass upon the bearing the lesions found might have upon the state of the subject's mind, and, therefore, do not offer an opinion.

Respectfully submitted,

J. W. S. ARNOLD,
E. O. SHAKESPEARE,
J. C. MCCONNELL.

SEPTEMBER 4TH, 1882.

Dr. Lamb furnishes the following measurements of Guiteau's skull:

Cranium of a male, age nearly 41.

Internal capacity,	1530 cc.
Length,	182 mm.
Breadth,	144 "
Breadth of frontal,	97 and 125 "
Height,	133 "
Index of foramen magnum,	45 "
Frontal arch,	290 "
Parietal arch,	323 "
Occipital arch,	243 "
Longitudinal arch,	380 "
Circumference,	521 "
Length of frontal bone,	127 "
Length of parietal bone,	135 "
Length of occipital bone,	183 "
Zygomatic diameter,	125 "
Facial angle,	71°

Skull, mesocephalic.

SOCIETY PROCEEDINGS.

AMERICAN DERMATOLOGICAL ASSOCIATION.

Sixth Annual Meeting, held at Newport, R. I., August 30th and 31st, and September 1st, 1882.

THE American Dermatological Association held its sixth annual meeting at the Ocean House, Newport, R. I., August 30th and 31st, and September 1st, 1882, holding morning and evening sessions daily. DR. JAMES NEVINS HYDE, of Chicago, President, and Dr. W. A. Hardaway, of St. Louis, Vice-President, presided over the deliberations of the Society.

AUGUST 30TH—FIRST DAY.

After a short business session, with closed doors, the morning session was opened by the following

ADDRESS BY THE PRESIDENT, DR. JAMES NEVINS HYDE,

Gentlemen of the Association: It becomes my agreeable duty to utter a few words of greeting and welcome at the opening of the sixth annual meeting of the American Dermatological Association.

The mere announcement of this fact suggests to us that this is an occasion for congratulation. The survival, for even this relatively brief period of time, of any special association of American physicians, ought in some measure to demonstrate that it had occupied its ground and was giving promise of a future. But when such an association is in position to give a good account of work actually accomplished, surely this supplies both a reason for its existence and an argument for its perpetuity.
